THE SURGICAL TREATMENT OF IMPERFORATE HYMEN.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-Second Annual Meeting of the American Medical Association, held at Washington, D. C., May 5, 1891.

BY JAMES F. W. ROSS, M.D., C.M.,

LECTURER ON ABDOMINAL SURGERY, UNIVERSITY OF TORONTO; ON GYNECOLOGY, WOMAN'S MEDICAL COLLEGE, TORONTO; GYNECOLOGIST TO TORONTO GENERAL HOSPITAL, TORONTO DISPENSARY AND ST. JOHN'S HOSPITAL FOR WOMEN, TORONTO.

In looking over the ordinary text-books in the hands of practitioners and students of the present day, you will find that the subject of imperforate hymen is passed over in most imperfect and unsatisfactory manner. By a strange coincidence, a professional colleague had asked my opinion regarding a case that died after operation for this condition, and in a day or two I was sent for by another physician to see the following case:

Mrs. F. H., æt. 20, seen July, 1890. Been married for sixteen months. Looked flushed. Has never menstruated. Suffers from spasmodic pains like labor pains. Was much worse last night than she has been yet. Her mother has been dead for some years, and she therefore refrained from consulting any one about herself. For four years she has felt pains like those experienced by her friends when they are unwell. They come on irregularly every two or three months. Has noticed a gradually increasing swelling over lower abdomen. The cramp-like pains have only come on recently. Would never permit her doctor to examine her, though after marriage she thought all was not right. Had difficulty in passing water. On examining the abdomen I felt what I took to be the uterus $1\frac{1}{2}$ inch above the umbilicus, and readily diagnosed imperforate hymen with retained menses.

After telling the husband of the dangers of operation, and after removing her into the hospital, I passed in a trocar, then cut out a circular piece of the $\frac{1}{4}$ -inch thick hymen, and before allowing much of the fluid to escape, inserted the nozzle of a syringe attached to a well elevated douche pail. In this way a large quantity of water was run in, until all the treacly discharge had been washed out, and with it large flakes of dead vaginal epithelium. While the cavity was

still distended with fluid, I began to pack it full of iodoform gauze, and as the gauze was packed in the water of course came out. No pressure was allowed above on the abdomen. This was all done with the patient anæsthetized, so that I could work under the most favorable circumstances. I stitched with a continuous suture the mucous membrane on the internal and external surface of the hymen, so that the subsequent passage of gauze would be more readily accomplished. The cavity of the pelvis was thus filled with gauze. This was only removed and renewed every forty-eight hours. After each removal the parts were thoroughly douched. The parts below were covered with an absorbent antiseptic pad. The patient was kept in bed for two weeks, and was never allowed to sit up. There was no rise of pulse or temperature, and her pains were at once relieved. She was not allowed to do any work for one month, and was specially warned against straining or lifting.

A peep into the aforementioned text-books may make such details appear unnecessary, but the sad experience of my colleague with his case terminating fatally, as it did within a few blocks of the hospital during the same week, made me extremely cautious. The fatal case improved, and was allowed to sit up on the seventh or eighth day; sudden pain seized her and she developed symptoms of acute peritonitis. In a short time she was a corpse. This death impressed on my mind the necessity of following out two points in the treatment:

1. A replacement of the fluid by something that will be antiseptic, soft and unirritating, harmless, and that will afford good drainage and sufficient support.

2. That when sudden symptoms occur at a late period from sitting up, sudden straining, coughing, etc., the quicker the patient's abdomen is opened and drained the better. Such cases have tubes that have ruptured or leaked on account of a disturbance of their adhesions.

Such a treatment is to my mind an ideal one. The patient must be anæsthetized to carry it out. Her abdominal muscles will thus be relaxed, and the tension on the pent-up fluid will be lessened. The orifice in the hymen can be thoroughly dilated, and a small speculum can be introduced to

facilitate the washing out and the packing with gauze. If the gauze is put in as it should be, in one continuous strip, it can readily be removed.

Should the symptoms of sudden rupture of some adhesions of the tubes, or escape of fluid through the tubes set in, with peritonitis, I should at once open the abdomen and look for the source of the trouble. Dilated, diseased tubes should be removed, and the abdomen washed out. One must, however, distinguish between the symptoms that are due to a *septic* inflammation affecting vagina, uterus, tubes, ovaries and peritoneal cavity, ascending from below, and peritonitis due to ruptured adhesions or escape of fluid into the peritoneal cavity. In the septic cases the vagina becomes tender and thickened, the uterus enlarged, tender and soft, cervix swollen, and the whole uterus appears as it does just after a labor is terminated. These cases simulate the ordinary cases of septic fever subsequent to labor, or our puerperal fever. One such has been recorded by Sir J. Y. Simpson. In the other form of complication the symptoms are sudden in onset and follow some indiscretion. Opinion as to the best surgical procedure in these cases of imperforate hymen is probably even yet divided. These cases usually fall into the hands of the general practitioner, and he is called upon to relieve them. He should, therefore, be perfectly familiar with the dangers to be met and the best methods of avoiding them. Let him take to heart the warning of Sir J. Y. Simpson: "Beware of making light of such a case to the patient's friends, and beware above all of telling them that the operation you are about to undertake is either harmless or trivial."

Let him remember that Dr. Matthews Duncan advises that the patient should be kept in bed for three or four weeks after the operation, to avoid the increase of intra-abdominal pressure that accompanies the erect posture. Any one who is skeptical as to this pressure may readily satisfy himself by watching the changes in a column of water communicating with the bladder through a catheter, during the recumbent and then during the erect position.

In these cases Barnes, that best of gynecological writers, says: "A free external outlet would make it easier for the contracting uterus to expel its contents by this route, and thus take off pressure towards the tubes. On the other hand, the rapid retreat of the uterus would favor the laceration of the tubes if held back by adhesion. The balance of advantages and disadvantages of either plan is difficult to strike; and it is to be apprehended that cases will continue to occur in which a fatal result will follow any method of treatment." Barnes and Simpson give very sound and practical opinions on this subject. Simpson and Matthews Duncan advise against washing out the cavity, while Barnes says that he is not quite

sure but that free incision and washing out is the best plan. Tait is in favor of washing out after free incision. He reports six cases done in this manner, and four done by the gradual method, without any fatal case. Emmet records four cases with four recoveries, but gives no details.

I have run through as much of the literature of this subject as I can command, and hoping that others may follow with more extensive lists, I have constructed a rough table of thirty-six cases with three deaths, a mortality of 8 per cent. The operation thus ranks with some of the most serious in surgery. I do not count the case of Thompson, where the condition was not discovered until after death from another cause, viz.: miliary tuberculosis. Four cases had subsequent severe peritonitis, to which two succumbed. Two had subsequent severe septicæmia, to which one succumbed. Again, to classify these differently, one died after free incision from peritonitis, produced by escape from the tubes. One died after free incision, washing out and apparent recovery, from some internal rupture and peritonitis. One died from septicæmia after the gradual method of evacuation, without washing out. One had severe peritonitis after the gradual method of evacuation, with recovery. One had severe peritonitis after the rapid method with washing out done twenty-four hours after, with recovery. One had severe septicæmia after the rapid method and washing out, with recovery.

Eight cases of the gradual method are recorded, against twenty-four of the rapid method.

In four cases the patients complained of dysuria. In three retention of urine was a prominent symptom. In one of the cases mentioned by myself a doctor was called in on a previous occasion, diagnosed retention of urine, and passed the catheter. The true condition was not recognized. This also happened in Drysdale's case.

Attention was usually called to the tumor when about the size of the gravid uterus at five months.

The effect of heredity is spoken of by Yates. He cites two cases occurring in two sisters and in two cousins of these two sisters. From what follows regarding the curious freaks of nature in his district, one concludes that it must be a curio-hunter's paradise, and the record loses weight.

But the strangest freak of all is to read in the "American System of Gynecology," that the prognosis is always favorable unless the patient has already had intra-pelvic hæmorrhage. I hope the writers of text-books will grant more than four and one-half lines to this subject. Cases are few and far between, and therefore our practitioners should be in possession of all the facts concerning them.

My ideas, then, as to the proper method of procedure, are as follows.

1. Warn the husband or friends of the danger of the operation.

2. Give the patient an anæsthetic.
3. Incise and tear the hymen freely.
4. Wash water in at once to take the place of and to wash out the blood and *débris*, and wash until the water comes out clear. Several quarts will be required.

6. Stitch the internal and external mucous surfaces of the hymen together.
7. Apply an antiseptic pad to the genitals.
8. Remove the gauze in forty-eight hours, wash out cavity, reapply gauze.
9. Keep the patient in the recumbent posture for two weeks, and in bed or on a sofa for a week or ten days longer.
10. If symptoms pointing to ruptured or leaky tube, with accompanying peritonitis, set in, open the abdomen, remove the cause of the peritonitis if possible, wash out the peritoneal cavity, and drain. To be successful this must be done early.

HYSTERORRHAPHY.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 5-8, 1891.

BY WM. RAWSON CHUNN, M.D.,
OF BALTIMORE, MD.

During the past few years, many things have been accomplished by the medical profession, having in view the prevention as well as the amelioration of suffering in mankind. I take pleasure in going a step farther, and doubt not that all rejoice with me when I say the same is true in regard to womankind. It is not necessary to mention by name all the advances in this direction, as time alone prevents, but by way of example we may say, without fear of contradiction, the barren woman is made to bring forth children, and she that had an issue of blood is healed of her infirmity. I need say no more by way of compliment, than that which was heretofore assumed to be miraculous is now nothing more than natural, and known to all. These results have been accomplished both by accident and design. Opportunity, quickness, manual dexterity and wealth, may be considered among accidental advantages. Out of these, however, proceed familiarity, confidence, experienced judgment, and last of all, design.

The histories and operations mentioned here are, to most of us, not at all novel or in any way startling. Although genius deserves, and sometimes obtains, credit for creating the brilliant and original, it is, fortunately, left for each member of the profession to try the experiment for himself; and thus, by the aggregate of individual effort, a true judgment is finally reached as to how much benefit is conferred upon humanity at large. Each one, then, has the right to give the result of his experiments, be they successful or otherwise, in order to make up this aggregate. For some time I had been looking out for a case where, in my judgment, it would be proper to attempt to cure a uterine displacement by fixation to the abdominal wall. It occurred to me, in order to prevent adverse criticism which might possibly be offered, that it would be well to select

5. Pack the cavity full of iodoform gauze. Use no compression on the abdomen.

a case where laparotomy was imperatively required otherwise than for the uterine malposition, such a case having hardly anything added to its gravity by the slight additional operation of fixing the uterus to the abdominal wall. It is here hardly necessary to state the various malpositions requiring the operation, except to mention posterior displacements, accompanied by persistent menorrhagia and metrorrhagia, continual miscarrying from retroflexion, distressing impaction of enlarged uteri in the pelvis, also not forgetting cases of decided prolapse and procidentia where the uterus descends between the thighs. About fifteen months ago, the case I had been looking for presented itself, and the following history was obtained: The patient was 28 years of age and unmarried, and had never been pregnant. For some two or three years past she had suffered greatly at her menstrual periods, and for nine months before I saw her she had been bleeding continuously. Of course, there were all sorts and kinds of pains in the pelvis. It was the bleeding principally, she wanted, however, to be cured of. Upon examination, the uterus was found enlarged and retroverted, and the ovaries could be distinctly felt, enlarged and tender, on each side. I considered Tait's operation would have to be done, but before resorting to the radical method, determined to dilate and explore the cavity of the uterus, and to use the curette, in hopes of relieving the neuralgia. This was accordingly performed, but resulted in no good, for the bleeding speedily returned, and was as bad as before the operation. I should say that it was impossible for the patient to wear a support, as the parts were entirely too sensitive to bear pressure. After some time had elapsed, and after the exhibition of the usual drugs with no change for the better, a day having been fixed for the operation, I repaired to the house of the patient and, with the assistance of Dr. E. M. Wise, Dr. L. E. Neale and others, prepared to take out the ovaries and tubes and stitch the uterus in the abdominal incision. The belly was laid open, and the tubes and ovaries were finally torn loose from their attachments and tied off on each side. Dr. Neale remarked that Tait's operation in this case was as justifiable as in any case he had ever seen. At this particular moment the patient ceased to respire, much to my discomfiture, and it was only by vigorous efforts that collapse was prevented. This accident, so to speak, "took my nerve," and instead of completing the operation after the manner of Kelly, by catching up the ovarian ligaments, I finished the operation by the following method. It is proper to state here, that the lower end of the abdominal wound was made as close down to the bladder as safety would permit. In stitching up this wound the first suture was introduced at the lower end of the incision, next the bladder,

and then carried directly through the top of the fundus of the uterus, and out again through the opposite lip of the abdominal incision at a corresponding point. In other words, this suture was simply the suture nearest the bladder, and which also held the uterus in its new position. It closed the lowest part of the abdominal incision, and anteverted and brought forward the uterus. A thin, straight needle was used, and a stout thread was threaded directly in the eye of the needle. By this means the thread was more easily carried through the dense uterine tissue, and the suture being somewhat larger than the needle, made sufficient resistance to prevent cutting out. At the same time, the thickness of the thread filled completely the track of the needle, and consequently there was no hæmorrhage. This ligature was composed of Chinese twisted silk, and in size was about as large as that usually used to tie ovarian pedicles.

There being no evidence of hæmorrhage in the pelvis, the rest of the incision was closed in the usual way. Drainage was thought inadvisable, as a tube, if close to the fundus, might have a tendency to prevent secure attachment to the abdominal wall. A vaginal examination was made immediately after the operation, and the cervix was found far back in the hollow of the sacrum, the body of the uterus lying on top of the anterior wall of the vagina and fast to the bladder end of the parietal incision. The patient was put to bed and allowed to empty the bladder at will, without the use of a catheter. She received no medicine and had no bad symptoms. The bladder performed its function normally and without irritation, and I did not see her again until the sixth day after the operation. I then removed all the stitches, with the exception of the suture holding the uterus, and found good union all along the line. After fourteen days the uterine ligature was also removed, the uterus still remaining in good position. The woman got out of bed at the usual time and began to go about, a pessary having been introduced as a precautionary measure. The support was kept in position about one month. The menorrhagia and metrorrhagia ceased at the time of operation, and have not since returned. This operation was done a year ago last January, and I did not see my patient again until March, 1891, fourteen months after she was operated upon. About the middle of last March she returned to the city, and I examined her at my office. The uterus was then found in normal position, slightly anteverted, with an attachment to the abdominal wall, which was somewhat movable. The cervix was back in the hollow of the sacrum, and the fundus could be plainly felt above the anterior vaginal roof. The traces of the abdominal incision had almost entirely disappeared. Menorrhagia and metrorrhagia had been entirely absent since the opera-

tion. Pain and other pelvic symptoms had disappeared, and the woman seemed restored to her usual state of health. Although uterus and vagina were undergoing atrophic changes, sexual desire was still present as before the operation, and she was not averse to marriage, provided a suitable party should make proposals.

I was interested to find that in this instance, where the uterus was kept in place after the operation, atrophy had taken place, whereas in another case, operated upon with the uterus left in a state of retroflexion, atrophy had not taken place as late as two years after the operation.

A number of procedures have been instituted by medical men within the past few years for the cure of posterior displacements of the uterus. Some of these I think will be found useful, others will doubtless prove without avail and be cast aside. It always seemed to me important to eliminate from the field, as soon as possible, any operation unlikely to be attended with success, in order that as few patients as possible should run the risks, without some certainty of a satisfactory result. In this connection I may mention the method of passing a suture, or sutures, through both abdominal wall and uterus without doing laparotomy. For those who are not experts, this method may seem without difficulty and free from danger. In order, however, to raise the uterus sufficiently to make the fundus impinge against the abdominal parietes, so that the proper direction may be given to the suture, manipulation of considerable skill is necessary, and although no lives have as yet been lost, I do not think this operation is without danger. My friend, Dr. Howard Kelly, was the first, so far as I know, to try the above mentioned experiment, and he tried it right along, in five cases, and after the ether, and it failed in every one. Now it strikes me that very few of us would have the courage to pursue such a course for such a length of time, and I feel like congratulating Dr. Kelly for eliminating from the field by his own efforts in such short order an operation destined to be of no benefit. It would be well if we could arrive at definite conclusions in regard to other operations with the same celerity. I should think the number of cases would be limited where the uterus could be stitched in place, without first opening the abdomen, retroflexion with adhesions in Douglas' cul-de-sac being a contraindication. It seems probable that some form of ventral fixation will in the future be the favorite means of treating the cases we are now considering, particularly as laparotomy is so many times imperative for other reasons. From the experience of others, as well as my own, I would not hesitate in any case to run a thread through the uterus and stitch it in the abdominal wound, where the abdomen had been opened on account of some more pressing emergency. I do not know what success has at-

tended the efforts of other operators by the use of a single suture, but if a single suture proves sufficient, it is all I ever expect to use. Reasoning from analogy, however, we should not expect too much from the operation. Sometimes the uterine stump, when treated by the clamp, after hysterectomy, will after awhile sever its connection with the abdominal parietes, although in such cases the attachment is most intimate. In hysterorrhaphy, however, the fundus and greater part of the uterus being present, the attachments may not have so far to stretch.

It seems hardly probable that a succeeding pregnancy would in any way interfere with the new position of the uterus (provided the ovaries and tubes remained normal), except, in fact, to lift it still higher up, and throw it further forward. When, for example, we consider how enormously the round ligaments lengthen during the last months of pregnancy, I think it safe to conclude that we can count on the same behavior of the uterine attachments after hysterorrhaphy. It is not my purpose here to give a detailed account of the operations embraced under the body of this paper, as the procedures are well enough known by this time to merit description in recent publications on that branch. It seems, however, that the different forms of operation may be divided mainly into two classes: 1. Those forms of operation where the supporting suture is passed through the round ligament, broad ligament, or ovarian ligament, etc., and then tied to the abdominal parietes; and 2, where the supporting suture is passed directly through the fundus of the uterus. It would give me pleasure to hear the opinion of the Association as to which of these forms is likely to prove most beneficial—and no matter which way the verdict stands, I shall be equally well satisfied.

TREATMENT OF ECTOPIC GESTATION.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY E. E. MONTGOMERY, M.D.,
OF PHILADELPHIA.

While it is important in every class of disease to have definite ideas as to the methods of treatment, it is particularly so in the condition under consideration. The obscure character of the symptoms often presented, the difficulty of diagnosis, the grave lesions resulting from development and rupture, render such cases so important, that time devoted to their consideration, even though it may lead to frequent reiteration, is not time lost.

A fierce conflict has been waged during the last few years between the advocates of surgical procedure and those who favor palliative measures. The latter class, recognizing the dangers

of a surgical procedure which necessitates the opening of the abdominal cavity, the separation of vascular adhesions, and the increased avenues for septic infection, have endeavored to seek some way by which they may be averted. To accomplish this, the general methods of procedure have been the injection into the sac, or into the fetus, of material which will bring about its death through poisonous action; or the destruction of its life by the application of the electric current. The first method of procedure has been the injection into the sac of morphine, chloride of zinc, and other agents. This plan of treatment, however, has been attended with such unpleasant results as a rule, that it is not now generally practiced. The injection of the chloride of zinc, has, however, been recommended during the past year as being an efficient method of destroying life and preventing further discomfort from the presence of the mass. The tendency of the development of suppuration and of inflammation extending to the surrounding structures, is such as to preclude its use. The procedure very frequently results in conditions which necessitate subsequent operation when the patient is far less able to undergo it.

Electricity has still many persistent and able advocates, who regard it as perfectly efficient in destroying the life of the fetus. There are, without doubt, many well authenticated cases in which its use has resulted in the death of the embryo and the arrest of its subsequent development. This being the case, it will be asked, why should not electricity be the agent we use for the treatment of such cases, rather than subjecting the patient to an operation, which, without question, is attended with a certain amount of danger. In answering this question we have, necessarily, to consider the progress of ectopic pregnancy and the difficulties in its diagnosis. It must be remembered that there is nothing in the earlier stages of ectopic pregnancy that would lead the physician, or even the patient, to suppose that the pregnancy was other than a normal one, and it is only when symptoms of danger threaten, and either partial or entire rupture has taken place, that the patient becomes aware of the gravity of her condition, and feels it incumbent upon her to consult a physician.

Rupture of the sac in a tubal pregnancy may take place at any time between the third and thirteenth weeks. In the earlier periods the first premonition the patient may have will be a tearing pain in the side, followed by a sensation of faintness, possibly repeated attacks of faintness or even fainting, and all the symptoms of internal hæmorrhage. In such a case the physician has no time for tentative measures, but must resort to a radical procedure in order to save the life of the patient. We have no reason to believe that the death of the embryo in the fetal sac in any

other portion of the tract would differ from that which takes place in the cavity of the uterus. Here, it is true, the fetus may die, may undergo the process of maceration and entirely disappear, but its envelope remains and may continue to retain its vitality for a number of months subsequently, before it is thrown off.

2. It is true the sac formed in the tube or ovary may not be so readily eliminated, but it remains an organized mass, which the organism of the patient must, sooner or later, be called upon to take care of, and hence it is likely to result in the development of trouble of such a character as ultimately to necessitate operative procedure for its removal.

3. Electricity, in cases in which the diagnosis is correct, is not an absolutely certain agent to destroy fetal life, but the embryo may continue to develop notwithstanding very strong currents of either galvanic or faradaic electricity have been used.

4. In many of the cases in which electricity has been used with a supposed successful result, it is doubtless true that the sac had already ruptured and the death of the fetus occurred, and the subsequent recovery of the patient was only the result of natural conditions, and not at all influenced by the application of the agent itself.

The writer was formerly an earnest advocate of electricity in the earlier stages of ectopic gestation, and in one case in which the diagnosis of extra-uterine pregnancy had been made, the faradaic current was repeatedly used without having any apparent influence upon the condition of the mass. Fearing to trust longer to such measures an operation was done, when it was found that the sac had ruptured, evidently before the electricity had been applied at all, and that we had an encysted mass in the pelvis, filled up with clot and debris of the embryonic development. In this patient the ovaries and tubes were removed, the abdominal cavity freed from its clots, thoroughly irrigated, and drainage practiced, with the subsequent recovery of the patient.

More careful study and experience in the progress and development of ectopic pregnancy, seems to us to indicate more clearly the importance of early resort to abdominal operation or radical procedure for its relief. Abdominal section is absolutely indicated in every case in which indications of rupture and hæmorrhage are present. In such cases time is of the greatest value. A collapsed and enfeebled condition of the patient may tempt the operator to endeavor first to overcome the effects of shock before subjecting her to operation, but what would be thought of the surgeon, who, when called to see a patient, suffering from rupture of a vessel of large size, which was pouring out the life-current, should neglect to resort to instant measures for its arrest? Incision and ligation of the bleeding-

vessel is just as absolutely indicated when hæmorrhage is taking place internally as if occurring externally.

May 13, 1890, I was called to see a patient 40 years of age, mother of twelve children, who had had a miscarriage eight months before. She had menstruated some five weeks before. The night before I saw her she went out to an entertainment, and was taken with violent pain in the side and faintness. She fainted several times during the night. When seen she was bloodless, pulse feeble, and unable to raise her head from the bed. The abdomen was large, pendulous, and gave negative symptoms upon vaginal and abdominal palpation. Believing that she was suffering from internal hæmorrhage, an incision was made. Two quarts of liquid and clotted blood were found in the cavity. In the left tube, rupture of a cyst the size of a cherry had taken place, and from it the hæmorrhage resulted. The tube was removed, irrigation and drainage used. The patient had an uninterrupted convalescence.

The ligation of the vessels, the emptying out of the abdomen, of the accumulated blood, the irrigation of its cavity with hot water, the stimulation of the flagging nerve centres with hypodermic injections of strychnine and the application of external heat, would be the measures which would give the most certain promise of relief to the suffering patient. When rupture has not yet occurred and the symptoms indicate the presence of an ectopic gestation, our treatment will depend somewhat upon the stage at which it comes under observation. If before the fifth month a section should be made as early as possible, and the foetal sac with its contents removed. This should be done for the reason that we have developing a foetus in such a position as to give rise to the greatest danger to the mother with the least reasonable probability of its safe continuance to viability.

After the fifth month the pregnancy may be permitted to continue until near the completion of a normal pregnancy, with the hope that a living foetus may be delivered. In the operation for the removal of such a foetus great care must be exercised to prevent hæmorrhage. Where it can be done, the seat of the placenta should be encircled with ligatures before this organ is removed. The placenta may be removed by rapidly peeling it off from its base and arresting hæmorrhage by gauze packing.

In other cases where it has a broad base, and severe hæmorrhage is feared, it may be preferable to permit the placenta to remain and be subsequently thrown off. The sac in such cases should be sutured to the abdominal wall, so as to exclude the peritoneal cavity in the subsequent progress of the condition, and thorough drainage should be secured. If the foetus be dead it is

better to postpone operation for its removal until after six weeks or two months, when the circulation in the placenta will have become occluded and there is much less danger from hæmorrhage. Where the foetus has been dead for a length of time and has become encysted, it is preferable that the operation should be done while the patient still remains in a healthy condition, rather than to wait until through some action or changes that have taken place in the sac and its contents, serious inflammatory conditions may be present which will greatly complicate the removal and the subsequent convalescence of the patient.

If following suppuration of the sac, sinuses have formed through which portions of the bones of the foetus have been discharged, the best results will usually be obtained by dilatation of the sinus and removal of the remaining portions of the fetus found within, irrigation of the sac and subsequent drainage.

A CERTAIN CLASS OF OBSTETRIC CASES IN WHICH THE USE OF FORCEPS IS IMPERATIVELY DEMANDED.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, Washington, D. C., May 5, 1891.

BY AUGUSTUS P. CLARKE, A.M., M.D.,
OF CAMBRIDGE, MASS.

Among obstetricians there is a conviction deepening more and more by experience, that whenever a preference is to be made between the use of forceps and a resort to internal version, the forceps should be chosen. The danger will be much less not only to the child but also to the mother. The risk that the child be born asphyxiated, and often, the difficulty if not impossibility of establishing artificial respiration, when internal version is had recourse to, are admitted by all accoucheurs. Even when in that class of cases in which there is much deformity, or unusual narrowness of the pelvis, the forceps is safer than version. In offering this statement, in favor of the choice of forceps, it is not on the ground that greater skill is required in the management by version, but because statistical reports of the masters of almost every country show that great risks are incurred by the employment of this method. All are aware that the forceps, within a comparatively recent period, has been used much more frequently than formerly. The adoption of the practice has assured greater safety in parturition; the mother has escaped many dangers, the mortality has been greatly reduced, and suffering has been more or less diminished. The timely use of forceps has also resulted in great saving of foetal life. It is said as an objection, that the forceps

has often been used to terminate labor that was in all respects progressing favorably. Admitting that this may sometimes have happened, we are taught, nevertheless, the fact that the obstetrician, having known the advantages to be derived by the forceps, and guided, as we must presume, by an intuitive instinct in the conduct of the right doing, has sought only to minimize a suffering, which to the minds of those less appreciative, would be regarded only as the development of the normal physiological function. Influenced in conduct by such motives the question arises, in what class of cases is the use of forceps imperatively demanded? Formerly the chief indications for the use of the forceps were the undue resistance from the soft parts, the debilitated condition of the mother, and the occurrence of convulsions. The indications here enumerated fall far short of comprising the conditions in which the forceps is now required. Within a recent period great improvements in obstetric practice have been made. The skill exercised in the development of surgical instruments generally has given us important improvements in the construction of forceps; consequently many cases of protracted labor, which would have heretofore been left to other methods of procedure, can now be happily terminated by the timely use of forceps. When the head of the foetus has descended into the cavity of the pelvis, and the labor has become lingering from uterine inertia, the forceps may be used with the greatest advantage. In protracted labor when the foetal head has engaged the pelvic brim, or has only reached that introitus and become arrested in its descent, the forceps should be preferred to all other means for relief. The necessity for the application of the forceps in such cases implies the existence of a normal, or a nearly normal, proportion of the pelvic cavity. In the case of Mrs. B., aged 23 years, who was confined March 10, for the fourth time the foetal head engaged in the pelvic brim, but could make no further descent. The pelvis, however, was well formed; the antero-posterior diameter was three and one-half inches, and the transverse nearly four inches. The position was occipito-anterior.

Regular recurring pains continued until some time after the cervix had fully dilated, and the membranes had ruptured, and the head had engaged the pelvic brim. After this, by some cause, apparently from the breadth of the shoulders and the size of the head, the case did not progress. Ether then being administered and the long forceps applied, labor was brought to an easy and speedy termination. The child was strong and did well. The mother suffered from no serious inconvenience. In her third confinement I was called in attendance. A similar condition of things obtained, except that the os, or rather the cervix, was slower in under-

going dilatation. Ether was given and the long forceps was used, without any mishap. In her second confinement I was also in attendance. The patient was much longer in labor; the position of the head was unfortunately occipito-posterior, and the head did not readily engage, but rested on the pelvic brim. The long forceps was called into requisition and delivery was successful. During her first confinement I was not in attendance. From the history of the case it appears that the patient was some twenty hours in labor. The forceps had to be used. The child was born alive; the head, however, I was informed, was much disfigured.

In a case to which I was called March 15, the head entered the pelvic cavity, but failing to make further perceptible advance, forceps was used. The position was occipito-posterior; delivery was easily accomplished. Both mother and child did well.

In another case to which I was recently called, the liquor amnii had escaped early, and the labor was making but little progress. The os and cervix were only partially relaxed. The pains were unusually severe, and at times almost tetanic. Morphia used hypodermically, and the inhalation of ether served in some measure to overcome the rigidity of the uterine cervix, and to enable me to apply long forceps to the head which was resting on the pelvic brim. In a case to which I was called in consultation the patient had been in labor some eight hours; the membranes had ruptured, and the pains were severe and exhausting, but failed to effect propulsion of the head. Chloral and subsequently ether were administered. This overcame the uterine spasms, and also served to relax and to dilate the cervix. Owing to the rigid and irritable conditions of the uterus generally, a resort to version was deemed unsafe, both to the mother and to the child. Forceps of somewhat unusual length was finally chosen, and delivery was safely accomplished. In reviewing the obstetric practice which I have had for the past twenty-four years, I find that in the cases in which the head became arrested at or above the brim of the pelvis, the results of each of the various methods adopted for relief clearly show that the long forceps is to be preferred. In almost every case in which the head of the child was at the brim, or had rested upon it, if forceps sufficiently long was employed, delivery was accomplished without serious injury. In cases in which the head had not reached the brim, if the cervix was relaxed, and supra-pubic, and abdominal pressure was rightly exercised, forceps could be applied, and delivery safely effected. In giving the results of my experience I make no reference to cases in which the head was above the brim, when there was evidence at the same time that the child was not alive; nor do I intend to consider the class of cases in which

a preternatural presentation occurs. In every such case the medical attendant can be guided only by the history of the patient, his own experience, and the indications before him. In regard to the great resistance offered by the soft parts as an indication for the choice of forceps, other methods of procedure may be resorted to with the most beneficial effect. Ether, and in cases of suspected renal complications, chloroform, chloral, opium, or morphia, hypodermically used, and nitrate of amyl will often assist in overcoming the vulval resistance. The administration of any one of the above may be supplemented by ergotine or by a milder oxytocic. The recent advances made by the development of the practice of gynecology unmistakably show, that the great resistance which is sometimes offered by the soft parts to the descent of the foetal head, especially when such resistance occurs in the vulva, should not be overcome by the application of forceps. By the employment of force, undue distention, and laceration of the vulva and of the vaginal introitus, as well as the lower segment of the uterus, the tissue and vessels of the bladder, and also of the perineal structures, are liable to take place. In cases of posterior occipital presentation we have a different element opposing the descent of the head. After the head has entered the pelvis the force of the uterine pains becomes misdirected. In this class of cases it is seldom that the soft parts offer any considerable resistance. The employment of the forceps, as has been said, merely regulates the propelling force, and soon without producing any untoward results the child will be in the hands of the nurse, and every danger which can reasonably be apprehended is found to have been averted. In regard to that class of cases of protracted labor in which the head has descended to the pelvic brim, experience shows, if I mistake not, that the forceps is imperatively demanded. In a case of protracted labor in which the head has not reached the brim, and the child is still alive, the results of my experience are largely in favor of the forceps. For every such case the forceps selected should be of the required length, and of a curve adapted to the peculiar features of the pelvis. The following case, to which I was called in consultation, illustrates the advantages of forceps in high operations: Mrs. H., aged 35 years, had been in labor twenty-seven hours. This was her first labor. Her physician had been in constant attendance. When I arrived I found that the membranes had been ruptured and that the os and cervix had fully dilated. The head was considerably above the pelvic brim. After the patient had been profoundly etherized long forceps was applied, but as soon as traction was made the blades slipped because they had not been curved sufficiently to allow their convex edges to sweep the hollow of the sacrum.

Forceps with a sharper curve was more easily applied, and the patient was quickly delivered of a living child whose weight exceeded nine pounds. The patient recovered without serious, constitutional, or local disturbances. Occasionally I have been called in consultation to cases in which I was expected to apply forceps before the cervix had fully dilated. In all such cases I advise waiting and endeavoring to effect by some of the different means proper dilatation of the lower uterine zone. In cases of puerperal eclampsia in which it is deemed necessary to hasten labor, digital and manual dilatation of the cervix should first be accomplished. Then, if the head presents, whether at the brim of the pelvis or above it, the forceps should be used. In breech or footling presentations, after the head has descended into the pelvis, the forceps is often of the greatest benefit in expediting labor, and thus preventing asphyxia of the child. In deciding in any case as to the necessity for the use of the forceps careful consideration has to be exercised. In reviewing discussions on the subject we have noticed that the advantages and safety of the forceps has been variously estimated. In the practice of some, the forceps has been used as often as once in every four to six cases. The necessity for such frequent use may not seem unlikely to occur in the practice of those who are connected with lying-in hospitals, or in the practice of those who are often called in consultation. This frequent employment of the forceps merely for shortening the time of labor betrays lack of appreciation of the real advantages to be derived by instrumental interference, and also want of conception of the dangers, either immediately or remotely, that may follow in any case in which forceps has been brought into requisition.

A REPORT OF TEN SELECTED CASES OF LAPAROTOMY, WITH REMARKS.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY JNO. H. MCINTYRE, A.M., M.D.,
OF ST. LOUIS, MO.

The following brief report of laparotomies is made in the hope that its variety may not be wholly devoid of interest:

Case 1.—Mrs. D., æt. 38, presented herself at my office in the early part of April of last year, suffering considerable pain and inconvenience from a rapidly growing tumor in the abdomen, situated immediately to the right of the umbilicus. The growth was somewhat movable, and the size of a foetal head.

She presented an anxious expression, suffered from insomnia, and was rapidly losing flesh. A short time previous to this interview, a council

of several gentlemen had decided that her trouble was floating kidney, and had advised, and she had submitted to, tight bandaging with compresses, to keep the supposed floating kidney in place; this was worn for several days, until she rebelled on account of the pain which it occasioned.

As at that time there was no suspicion of anything of a malignant nature, and as I was on the eve of my departure for a month's absence, and she evidently needed "toning up," I left her in the care of my assistant, but advised removal of the growth by abdominal section, immediately on my return home—which I may mention was hastened several days on account of news of her rapidly increasing unsatisfactory condition.

May 29, she was anesthetized, and the abdomen opened in the linea alba, the incision extending from the umbilicus, to near the symphysis pubis. Upon passing my hand within the abdomen, over and around the tumor, I found extensive attachments. The ventral wound was extended three inches upward, and to the left of the umbilicus, and the growth turned out. It was attached to the mesentery, the intestines and the lower lobe of the liver by an intricate mass of adhesions, and was carcinomatous. Of course there was but one thing to be done, and that was to return it to the abdominal cavity and close the wound.

She rallied nicely from the operation, and much to my surprise the abdominal wound healed throughout nearly its whole extent by first intention, only a sinus remaining at the lower angle of the wound to give us trouble. I scarcely need say that she has since died.

Case 2.—On June 13, just fourteen days after my very unpleasant experience with the case above referred to, Mrs. A. E. A., æt. 32, who had long been a sufferer from ovarian irritation, with all its attendant ills, was placed on the table and both ovaries and the Fallopian tube of one side were removed through a two and one-quarter inch incision in the linea alba. Each ovary was not only inflamed and enlarged, but one furnished more than a tablespoonful of pus. The reaction was prompt, and the wound healed by first intention, all stitches being out by the seventh day. The cure in this case is complete; the lady goes into society, does shopping, and now superintends her household affairs, and is again the bright star in the beautiful and refined home over which she presides.

Case 3.—Mrs. R. C., æt. 29, rather fleshy, though always pale, had been a sufferer from ovarian irritation since she was 14 years of age. Her spine had been many times blistered, cupped and painted with iodine, croton oil, tartar emetic, etc. Her womb had been dilated—though for what real reason heaven only knows. She had been sent to Colorado, to the Hot Springs of

Arkansas, Eureka, and many others, but to no advantage.

She was anesthetized with bichloride of methylene used in a Junker's inhaler. An incision two and one-half inches in extent was made in the linea alba, and both ovaries and both Fallopian tubes were removed. She also rallied well, the ventral wound healing by first intention. She walked out, a block away to the corner grocery, on the sixteenth day; she is now in the enjoyment of excellent health, and so far with the sexual instinct the same as before operation. In both these cases of Battey-Tait operation there has been no return of menstrual flows.

Case 4.—Mrs. S. G., æt. 44; an anæmic, bed-ridden sufferer, with an enormous sub-peritoneal fibroma. Bowels could not be moved even by powerful cathartics and rectal injections, oftener than once in twelve to sixteen days, when they would suddenly run off for two or three days. This condition was occasioned by mechanical pressure, which produced irritation and inflammation, and caused many adhesions. The growth was removed through an incision extending almost from the xyphoid cartilage to the symphysis pubis. While breaking up adhesions very gently with my finger, I had the misfortune to split the softened gut to the extent of two and a half inches; fecal matter poured into the abdominal cavity, which was quickly cleansed by sponges squeezed out of a 1:2,000 mercuric bichloride solution. Placing my finger in the rent, the tissues were so softened that the tear extended at least another inch in extent, making three and a half in length. It was closed up with silk, using the Lembert suture.

When the operation was completed she was almost moribund. About a dozen and a half hypodermic syringefuls of brandy were thrown under the skin in the arms and legs, she was put to bed and her body and limbs surrounded by hot water. Reaction was obtained slowly but perfectly, and recovery was uneventful. A stitch-hole sinus gave the only real trouble, and did not close for over four weeks.

Case 5.—October 16, 1889, I received a letter by messenger from a medical gentleman, urging me, if possible, to meet him, together with two others, in consultation, immediately on the arrival of the train. He said, "my diagnosis is uterine tumor, probably fibrous. She is suffering intensely with tenesmus of the bladder and rectum; something must be done early, and I hope you will be able to come this evening."

I found the doctor's fears to be indeed well founded. A lady of culture and refinement surrounded by every evidence of luxury, but was in a semi-unconscious state, with a temperature of 103°, suffering excruciating agony, which the most heroic doses of morphia only relieved by being frequently repeated. A tumor to all ap-

pearances hard and solid, protruded at the front of the abdomen, yet was jammed down in the pelvis, and its lower segments could be distinctly felt in the retro-uterine space.

Matters were indeed desperate, and although abdominal section gave but a ray of hope, yet it was decided to give her this slender chance. It was done the next morning, and we found a suppurating tumor, broken down in its entirety, which sprang from the left ovary, and pus, pus, pus everywhere. The operation lasted fifty minutes; she rallied gradually, and with no nausea, but although the temperature came down almost to normal, she died of exhaustion, and previous septic infection, on the fifth day after the operation.

Case 6.—Mrs. E. D. H., æt. 37. Since the birth of her only child, now 14 years of age, has never been "just well." About four years ago began to suffer much pain, and an unusual loss of blood at her menstrual periods. Matters went on from bad to worse, during which time she had gone the "grand rounds," consulting "regulars," irregulars and defectives. At the time of my first interview I found a woman nervous, anæmic and pale from loss of blood, spending one-half of her time in bed, and losing blood three weeks out of four; thus having only one week in the intermenstrual period in which to recuperate. Examination revealed the uterus enlarged to a size of that between the third and fourth month of pregnancy, the os quite low down, and the fundus and part of the body easily felt through the abdominal parietes. By bimanual palpation was easily made out its hard, nodular and irregular outline. The removal of the ovaries to bring about the menopause was promptly advised, and as promptly declined. Coupled, however, with the request that something be done other than a surgical operation. Much against my own judgment I consented to retain the management of her case, and during a period of four months following subjected her to many hypodermatics of ergotine introduced in the linea alba, with the advantage of producing two painful abscesses and no control of the hæmorrhage. I now informed her that temporizing, at least at my hands, was at an end, and that she must be governed wholly and absolutely by my advice, or I should retire from the further management of her case. A family council was held, which resulted in their acquiescence, and a laparotomy was performed the next day. Bichloride of methylene in a Junker's inhaler being the anæsthetic used. An incision five inches in length was made in the linea alba; introducing the hand into the abdomen, it was easy to make out six or seven hard multiple myomatous tumors, varying in size from that of an almond to that of a goose egg, imbedded in and protruding from the walls of the uterus; the ovaries were found and removed

without difficulty, and the ventral wound closed with silk-worm gut sutures. Recovery prompt and uneventful. Some show of blood at two or three menstrual periods following, but no hæmorrhage, cure complete. She is not a believer in hypodermic medication.

Case 7.—Mrs. R. O., æt. 25, was first a mother at the age of 19. Had been an invalid since the birth of her youngest child, now 4 years of age. Suffered from albuminuria; had "sinking spells" together with an enormous distention of the abdomen, for the relief of which she sought, not the Pool of Siloam, but the healing and rejuvenating waters of Lebanon, Mo., where she came under the professional care of my friend, Dr. J. M. Billings, of that place, who, recognizing her real condition, referred her to me for operation.

The doctor arrived the next day, but I suggested to him that on account of her unsatisfactory condition it might be well to postpone the operation for a few days (her temperature being two degrees above normal), when he replied, "you may as well proceed with the operation, for you will never get her in better condition; only a short time ago her husband was sent for to come to Lebanon to see her die."

Accordingly the operation was performed the day after his arrival.

Our diagnosis was unilocular cyst of the left ovary. Circumference of the abdomen over the umbilicus was 39 inches. Time of operation, one hour; weight of tumor, 36 pounds; it was multilocular, instead of unilocular as we had supposed.

There were extensive but not firm adhesions, which were abdominal rather than pelvic, the most troublesome being in the region of the liver. Pedicle was transfixed, ligated and pocketed.

The ventral wound was closed with sixteen silk-worm gut sutures. External dressings, antiseptic gauze, compresses and the time-honored flannel bandage.

Much to my surprise, I found her at 7 P.M., on the evening of the day of the operation, with a temperature of 98 degrees, and no vomiting.

The temperature did not go above 100 degrees until after the tenth day.

Ten sutures were removed on the seventh day, and the remaining six on the eighth, the wound having healed throughout by first intention.

On the evening of the tenth day the temperature suddenly went up to 102.5 degrees, and by the twenty-second, in spite of antipyretics, had reached 103 degrees, after which it steadily and rapidly declined to 98 degrees with the space of five days.

I accounted for the above condition as follows: At the time of the sudden rise of temperature the skin assumed a yellow tinge, and within twenty-four hours had presented the dark, yellow hue of a typical case of jaundice, continuing until the twenty-second in spite of all the medication which had been used.

I now became convinced that the trouble was occasioned by occlusion, more or less complete, of the ductus communis choledocus, on account of contraction of the raw surfaces which had been produced in breaking up adhesions in its vicinity, and that my patient would die if not relieved. So I resorted to no very gentle massage, over this particular region, and with the most happy effect, for within twenty-four hours the skin and conjunctiva had sensibly cleared up, and rapidly continued to do so until they had assumed their natural hue.

The temperature within the first twenty-four hours had fallen nearly 3 degrees, and as I before stated, was normal by the end of the fifth. After which she went on to a rapid and satisfactory recovery.

Case 8.—Mrs. F. C., æt. 45. When in good health a large, fleshy woman. Mother of several children. About four years ago noticed some change in her menstruation, it being increased both in duration and quantity. At first she gave it little thought, as she supposed she was reaching the climacteric.

Later on she noticed a small lump in the right ovarian region, together with an increase in the size of her abdomen. Yet, as she expressed it, she thought she must be again pregnant "in spite of herself." The abdomen continuing to enlarge and the period of pregnancy having passed, she realized the possibility of abdominal tumor of some kind.

Her general health now began to fail. She lost flesh, suffered from indigestion, and had many profuse uterine hæmorrhages, together with a rapidly increasing abdomen; and at the time I saw her, the *facies ovariana* was well marked.

At the preliminary examination of this case, I was at first a little undecided, on account of the uterine hæmorrhages and the nodular and somewhat irregular outline of the abdomen, whether it was an enormous subperitoneal fibroma, or a multilocular cyst. I finally, however, decided that it was a multilocular cyst, and had the satisfaction of confirming my diagnosis at the operation.

A tumor of 30 pounds weight was removed, which was partly solid, but having many compartments; the solid part furnishing a most beautiful specimen.

The pedicle, which contained two unusually large vessels, was transfixed, ligated and dropped back into the abdomen.

Wound closed by silk-worm gut sutures, and antiseptic dressings applied. Time of work fifty minutes. Some nausea, but no vomiting followed. Abdominal wound was inspected on the morning of sixth day; it having healed by first intention, without a drop of pus or a blush of inflammation. No rise of temperature at any time of over 2 degrees above normal.

Case 9.—On December 10th, 1890, Mrs. M. B., age 38, height five feet one inch, weight ninety pounds, was sent to me from a distance to have an unilateral laceration of the cervix restored.

She first menstruated at the age of twelve. Was married at 25. Is the mother of two children, the youngest being now seven years of age, from the birth of which she dates her ill health.

For the past five years has been absolutely unable to endure marital relations. Has suffered great pain and tenderness in right ovarian region, and, in a lesser degree, also in the left, together with weight and dragging in lower part of abdomen. Has suffered much from insomnia, palpitation of the heart, and is very melancholy. Has been often confined to her bed for weeks at a time, the longest being from January to June of last year, at which time, as she expressed herself, she was "past pain."

She suffered much from menstrual headaches, and was seldom free from the peculiar sense of heat and weight upon the vertex, so characteristic of uterine and ovarian irritation. At the time of my first interview, I found a woman just upon the verge of insanity. One of the first things I did was to remove a horseshoe pessary from her vagina, which she had worn for many months. The little tear in the cervix amounted to next to nothing.

Some granular erosion existed on the os, and the uterus was inflamed and congested. With the right index finger in the vagina, and the left hand upon the abdomen, I could easily make out the soft, baggy and irregular rounded tumors, sausage-like, in the ovarian region, the right larger than the left, both being exquisitely tender, and although the examination was conducted with care and gentleness, yet she complained of nausea and faintness. She was, therefore, advised to submit to laparotomy for removal of both ovaries and Fallopian tubes.

After one week of rest and preparation, the operation was performed on December 17, 1890.

Bichloride of methylene in a Junker's inhaler being the anæsthetic which I always use in my abdominal operations, was of course the chosen one. Through a two and one-half inch incision in the linea alba, the left tube and ovary was easily removed. Not so, however, with the right, as it was prolapsed deeply into Douglass cul-de-sac, and was bound down by many and rather strong adhesions. After being brought out through the ventral wound, I found not only an enlarged tube, but also a beautiful specimen of hæmatoma of the ovary, in size about as large as a turkey's egg.

I wish here to call the attention of my professional brethren to the excellence and safety of Mr. Lawson Tait's Staffordshire knot in the ligation of the pedicle.

The ventral wound was closed with silkworm

gut sutures introduced from within outwards. The patient rallied nicely, and, as is usual in my experience with the anæsthetic used, with no nausea.

Her recovery was eventful, the temperature at no time going above 101 degrees. Sutures were all out by the seventh day, and she returned to her home in one month after the date of operation.

A gratifying feature in this case was the prompt amelioration of all her unpleasant nervous symptoms—within a week after operation the expression of her countenance was markedly changed. She became bright and cheerful, and proved herself to be a woman of far more intelligence than I at first supposed her to be. I shall watch the after-results of this case with much interest.

Case 10.—Mary A. J., single, æt. 38, height 5 feet, 5½ inches, weight before operation, 199½ pounds. American, of rather masculine appearance, large bones, coarse features, having hair on the upper lip and chin. I found her in the poor house near Trenton, Grundy County, Mo., on November 26, 1890, suffering with a colossal growth of the abdomen, a good idea of which may be obtained from the photograph which I took at the time of my first interview.

Measurements taken at that time were as follows: Circumference at largest part just below umbilicus, 50 inches. Circumference just below the mamma, 35 inches. From xyphoid cartilage to symphysis pubis, 32 inches, not including the pendant appendum, which is shown in the picture. From xyphoid cartilage to umbilicus, 13 inches; from right anterior superior spine of ilium, to umbilicus, 14 inches; left anterior superior spine of ilium, 13½ inches. Circumference of pendulous portion of growth at neck just below symphysis pubis, 27 inches. Circumference at its base, 30 inches. The surface was smooth, tense and slightly elastic, large tortuous veins passing in various directions.

Percussion imparted a slight wave that almost suggested fluid within a sac. The uterus was drawn up to the extent of twelve or fourteen inches. She walked with great difficulty and with a waddling gait, bending far backward, the better to keep "the center of gravity within the base," and thereby be better able to sustain the enormous weight of her abdomen. She was compelled to pass her urine while standing upon her feet.

Attempts had been made six and two years respectively, before my first examination, to tap her, and although a large trocar was thrust into the growth at several points, yet nothing came out but a few drops of blood.

Diagnosis.—Either multilocular ovarian cyst or cedematous myoma of the uterus.

At the beginning of her enlargement she was supposed to be *enclente*, was spuried and cast off

by her family and friends, and after suffering many privations and hardships finally brought up in the poor-house, where I first saw her, at the solicitation of two prominent ladies from whom I had, during the past summer, removed large ovarian tumors.

Their attention being called to this poor unfortunate, and being actuated by that bond of sympathy "which makes all the world akin," they provided the means for her care and transportation to St. Louis, for operation, provided I thought best to do so. Although she was at the time failing rapidly, I saw that she had not the slightest ray of hope from any thing but an operation, and believing that the justifiableness of any operative procedure consists in its necessity, I advised her to accept the only chance, though a slender one, for her life, which she promptly did.

A few days later she was brought to this city by Dr. H. H. Wilson, of Trenton, Mo., and one of the ladies above referred to, and placed in the hospital.

During the few days of rest and preparation before operation, I requested Mr. Thompson to have her weighed. The following was received from him:

ST. LOUIS, December, 6th, 1890.

Dr. McIntyre:—Your case, Miss Mary E. Johnson, in room No. 10, was weighed by me at 9:50 A.M., and tilts the beam at 199½ lbs., good weight. Respectfully,
F. P. THOMPSON.

On the morning of December 7th, 1890, the operation was performed with the assistance of Drs. Broome, Marks and Nichols of this city, and Dr. H. H. Wilson, of Trenton, Mo.; Drs. Gib, W. Carson, R. A. Quarles, P. S. O'Reilly, Moore and medical students Charles Lewis and F. P. Thompson of this city being present.

Bichloride of methylene in a Junker's inhaler, was the anæsthetic chosen. Anæsthesia was easily and promptly induced, and was maintained during the one hour and five minutes that the operation lasted, five and one-half drachms being used.

An incision fourteen inches in length was first made in the linea alba, below the umbilicus, and afterwards extended up to near the xyphoid cartilage. The hæmorrhage made by the incision in the abdomen wall was very free, and the enormously distended vessels required the application of a large number of pressure forceps. Adhesions were found almost everywhere, the most difficult to manage being those attached to the liver and diaphragm. The broad ligaments and Fallopian tubes were ligated on either side, the tumor turned out, the thick heavy pedicle transfixed and ligated, and the tumor cut away.

It is a matter worthy of remark, that at the time of detachment of adhesions to the diaphragm the patient sank rapidly, and as it was thought that she might die on the table, hypodermics of whisky were freely used before she rallied, and several minutes of time lost during the interval.

A stream of hot water was kept playing upon the wound during the whole time of operation.

The toilet of the peritoneum was necessarily hurried, and was greatly facilitated by pouring pitcher full after pitcher full of distilled water heated to a temperature of 110 degrees, into the abdomen. The ventral wound was closed with silk-worm gut sutures, adhesive straps applied across the abdomen; compresses and the time-honored binder completed the dressing.

As she was being carried from the operating room, through the hall to her bedroom, the stretcher was allowed to rest upon the platform scales for a few moments, and we found that we had 106 pounds of woman left, and as her weight before operation in the same clothing was 192½ pounds, we found that the weight of the tumor was 93½ pounds. Placed in bed she was surrounded by bottles filled with hot water, and free hypodermics of whisky used. Within a few hours she had rallied well and with no nausea.

This case was manifestly one for drainage, but on account of the vast expanse of lax abdominal tissue, I did not believe that red serum would gravitate into Douglass'-space sufficiently to re-

move it through the Kieth tube. I therefore remarked to the gentlemen present that if at any time the temperature went up so as to require it, we would cut a few ventral sutures and flush out the abdominal cavity. By the morning of the second day, forty-eight hours after the operation, the temperature in spite of antipyretics went up to 103.5. She was taken into the operating room and the abdomen flushed with hot distilled water, and many blood-clots and much serum removed, with the result that within six hours the temperature had fallen to 101°. A drainage-tube being now introduced furnished but little serum afterwards. Temperature did not go above 102 degrees for the succeeding twenty-four hours. Within another forty-eight hours, symptoms of septicæmia became manifest, together with septicæmic vomiting, and she died at 4 A.M., December 12th, the fifth day after operation.

REMARKS.

The lesson which I learned, and the regret which I have in the after-management of this case, especially after witnessing the lowering of the temperature and the amelioration of unpleasant symptoms after the flushing of the abdomen with a large quantity of hot water, is that I did not resort to it again, or indeed as often as might seem necessary, for she became bright and cheerful, took liquid nourishment well, and flatus passed the bowels, and I began to have high hopes of her recovery.

The ordinary drainage-tube did comparatively little good, as the enormously distended abdominal walls favored collections of serum in pockets, it did not gravitate into Douglass' pouch; consequently the peritoneum with its wonderful absorbing powers, which at once constitute its safety and its danger, took up septic material with fatal results.

In looking over the literature of this subject I find no mention of any solid tumor of this size being removed.

Keith, late of Edinburgh, now of London, successfully removed an œdematous myoma, together with the uterine, which was of 42 pounds weight, on the 18th of April, 1881.

Mr. Lawson Tait, of Birmingham, England, reports in Vol. 1, of his recent work, "Diseases of Women and Abdominal Surgery," page 187, that the largest uterine myoma which he ever removed in his life was of 68 pounds weight, and that it grew after the menopause. So, I believe that this one of my own, 93½ pounds, is the largest yet reported.

In all laparotomies I carry out the strictest antiseptic precautions, although I abandoned the spray six years ago, and I now get better results without it than I did with it. All instruments are placed in a large shallow photographer's dish containing a 1 to 40 carbolic acid solution, be-

fore and at the time of operation. Plenty of the finest quality of sponges, cup and flat, are kept for this operation alone, and are used in no other, and I give their cleansing and preparation my own personal attention. Bleeding points are ligated with fine Japanese cable silk. The pedicle is always ligated and pocketed. The ventral wound I always close with silk-worm gut threaded upon two long veterinary needles, and pass the needles from within outward, always including the peritoneum. The idea of its use I received more than ten years ago from Geo. Granville Bantock, of London. It is very strong and smooth, and can easily be made aseptic; being somewhat stiff, it should be steeped for a few hours before being used in a solution of some kind, so that there may be no difficulty in tying it tightly. It is the ideal suture, not only in closing the ventral wound in laparotomies, but also in lacerations of the cervix and perineum.

For inducing anæsthesia, I use exclusively bichloride of methylene in a Junker's inhaler, and now with an experience in its use in over three hundred operations of various kinds, while I have not infrequently seen nausea, I have only seen vomiting five or six times.

When in doubt I always drain, and prefer Keith's glass tube to all others.

I use but little opium or morphia, for the reason that this drug, by locking up the secretions, limits the power of elimination, and thereby favors septicæmia. For over a year past in cases of laparotomy where pain and rise of temperature was present, I have used antikamnia in ten grain doses with the happiest effects.

After doing the Battey-Tait operation a large number of times, I wish here to add my testimony to that of others, that removal of the uterine appendages does not entail a loss of sexual feeling; excitability of the genital organs still remains, the voice is unaltered, and the womanly attributes are no less after the artificial than after the natural menopause.

614 Olive St.

THE TREATMENT OF OCCIPITO-POSTERIOR POSITIONS.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D.C., May, 1891.

BY A. WORCESTER, A.M., M.D.,
OF WALTHAM, MASS.

The discovery of an occipito-posterior position is always a most unwelcome discovery. Even if all other conditions are favorable, this is unfavorable, and at best means a longer labor and an increase of all the dangers of exhaustion; while, on the other hand, in such cases, more often than in cases of occipito-anterior position, operative assistance is demanded, and yet can be given only with more difficulty.

In view of this greater probability that operative assistance will eventually be necessary, and in view also of the greater safety, to both mother and child, if such assistance be given early, I maintain, contrary though it be to generally accepted teaching, that, instead of being less ready, we should be more ready to assist the delivery in cases of occipito-posterior, than in cases of occipito-anterior, position.

I cannot, however, accept as very practicable the plan of rotating the fœtus from an anterior to a posterior position before labor begins. For, even if it is easy to do, it can be done only at the sacrifice of the mother's natural confidence that all is just as it should be with herself and unborn babe. Moreover, this rotation can be just as well performed after labor has begun, when the sufferer longs for every possible assistance.

In this paper I propose to consider the treatment only of such cases as are unlikely to progress favorably either if left to nature, or if assisted merely by flexing the head and favoring rotation manually. After briefly considering the six methods in common use, I hope to show that one of these methods, slightly modified, is pre-eminently advantageous.

1. Let us first consider podalic version. By this method delivery can be quickly effected. The only disadvantage is the danger of lacerating the parturient canal; or, if time sufficient for the stretching of the perineum be allowed, there is then the danger of suffocating the child. Probably in no other obstetric operation does the personal equation of the operator count for so much. And the skill which alone can insure safety to both mother and child can be gained only at the expense of many a perineum and many a fœtus.

2. By manual rotation of the occiput to the front, the original disadvantage of a posterior position can be eliminated. Where this can be done without anæsthesia, and at exactly the proper time, no safer method of treatment need be sought. But, if done too early, the head will generally rotate back into its original position before it becomes engaged; while, on the other hand, if artificial rotation is not attempted before the uterus has firmly grasped the fœtus, it becomes a very difficult task. Moreover, it is only in exceptional cases that manual rotation can be done without anæsthetizing the patient; and then there is an awkward interval before the uterine and abdominal muscles sufficiently recover from the anæsthesia to engage the head. During this interval the new position can be maintained only by holding with the hand. A more trying situation for both patient and accoucheur cannot be imagined.

Let us now consider the four methods of treating occipito-posterior positions by means of the forceps.

3. By applying the blades over the parietal

bones, the head can be delivered with the face under the pubic arch. This can be safely done where the head is fairly small in proportion to the size of the pelvis, and where the perineum is very lax. But inasmuch as it can be done only at considerable risk, and only by much stronger traction than would be necessary if the occiput were in anterior position, this method can be recommended only when previous manual rotation of the head is contraindicated. Practically, it is probable that in a large proportion of the cases where the head has been delivered by forceps with the face under the arch, the diagnosis of occipito-posterior position has been made post-partum.

4. With straight forceps, the head can be rotated while in the parturient canal.

5. By repeated applications of the forceps, as the head rotates during its assisted descent, the natural progress can be imitated. Not having employed either of these last two methods, I am not justified in criticising. The objections to each method are obvious, but there could certainly be no objection to practicing either upon the cadaver.

6. After manual rotation of the occiput from posterior to anterior position, the head can be delivered by means of the forceps, or can be drawn down into the pelvis in this acquired favorable position, and left for natural expulsion.

The only difficulties attending the employment of this method have been in conforming the traction to the axis of the parturient canal, and in maintaining the anterior position of the occiput while applying the forceps. The first difficulty, common to all high forceps operations, has been practically obviated by the use of axis traction instruments. And the second difficulty can be obviated by *applying the instruments under the guidance of the operator's hand inside the uterus.*

After the entire escape of the liquor amnii, and after the uterus has by its tonic contraction, or by its retraction, firmly grasped the fetus, or still worse, after the head is impacted in the pelvis, it is, of course, as impossible to rotate the occiput into anterior position as it is to do podalic version. The trouble in such cases, however, is due, not to the impracticability of the method here advocated, but to the mismanagement of letting pass the only time when the child's life might have been saved.

Until the child's life has been thus defaulted, it is certainly easy, with one hand in the uterus of the fully anæsthetized patient, for the operator to rotate the foetal head into anterior position. He may, of course, need the aid of his other hand, or of his assistant's hands, on the outside. If now the forceps can be properly applied, the disadvantage of the original position will be overcome.

In the use of forceps at the brim of the pelvis, unless the operator is exactly sure of the position

of the foetal head, of its complete flexion, and also of the location of the blades' impingement, it is a matter of luck if the delivery proves to be easy and safe. If there is difficulty in locking the instruments, or if, on traction, the handles separate, the operator of course will suspect that some mistake has been made in applying the blades. But the only way of being absolutely sure, and of rectifying any unfavorable condition, is by means of the whole hand inside the uterus. Now it is not practicable, after the forceps are applied, to introduce into the uterus the whole hand, but while the hand is inside the uterus, it is practicable, and safe, and easy to introduce and apply the forceps. The wrist and forearm of the operator, if rotated from his shoulder, allow each blade in turn to pass through the parturient canal alongside their sensitive flexor surfaces, thus beautifully guiding the blades into the uterus, where, in the palm of the operator's hand, each blade in turn can be applied to the elected area of the foetal head. Having then locked the handles, and having placed the head in the most favorable position as regards the pelvic diameter, the operator can then easily withdraw his hand alongside the shanks of the forceps.

If, now, axis traction appliances are attached, thus guarding against the dangers of traction in any tangent to the pelvic axis, the foetal head can be delivered, or, after having been drawn down into the pelvis, it can safely be left for natural expulsion. If by this method the child's life is not saved, the accoucheur may rest assured that the living child could not have been delivered *per vias naturales.*

In offering to the profession any new method, it is proper to give one's own experience therewith. I therefore add the reports of the four cases where I have employed the method advocated:

Case 1.—Mrs. B., primipara, 27 years old, had been in labor thirty-six hours when I was called by Dr. E. R. Cutler to help in her delivery, December 15, 1890. There was no engagement of the foetal head. Under the mistaken diagnosis of an occipito-pubic position, the forceps was applied, and we each in turn vainly tried to effect delivery. After removing the forceps, with the whole hand in the uterus, the position was found to be occipito-posterior. Without removal of the hand, after rotating the occiput to the front, the instruments were reapplied, the hand was withdrawn, and then the child was easily delivered in good condition. The posterior vaginal wall suffered a slight oblique laceration.

Case 2.—Mrs. R., primipara, 25 years old, had been in labor twenty-one hours when I was called in consultation by Dr. A. Greenwood, December 27, 1890. Her condition necessitated artificial delivery. Her pelvis was contracted; the distance between the crests of the ilia being $10\frac{1}{2}$

inches, between the anterior superior spines of the ilia $7\frac{1}{2}$ inches, between the trochanters $12\frac{1}{2}$, and the external conjugate diameter being $6\frac{1}{4}$ inches. Under full anaesthesia the dilatation of the os uteri was completed normally. The occiput was rotated from left-posterior to left-anterior position, and, without removal of the hand, the forceps was applied. Traction-rods were attached. After tremendous pulling, a male infant weighing 8 lbs. was delivered. His right eyelid was torn. With some difficulty he was resuscitated, but he died the next day, evidently from injuries received during delivery. The mother's vagina suffered several slight lacerations.

Case 3.—Mrs. H., quartipara, 29 years old, after several hours of ineffectual second-stage labor, was etherized, Dr. H. A. Wood assisting, March 24, 1891. The position of the foetus was occipito-right-posterior. With the whole hand inside the uterus, the position was changed to occipito-anterior, and forceps applied before withdrawing the hand. A male child weighing 10 lbs. was then easily delivered. The mother's vagina and perineum suffered no damage.

Case 4.—Mrs. C., primipara, 22 years old, had been in labor twenty-four hours, and the pains had almost ceased, when, with Dr. H. A. Wood's assistance, she was etherized. The foetal head had descended to the inferior straits in left posterior position. In spite of good flexion, there had been no sign of natural rotation. The head was thereupon pushed back above the pelvic brim, rotated to anterior position, and forceps applied to it before removing my hand. Extraction was then easy. The female child weighed 7 lbs. and was uninjured, although one blade of the forceps was applied to the right eyebrow. The mother was also uninjured.

THE MANAGEMENT OF THE OMENTUM IN ABDOMINAL OPERATIONS.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY ANDREW F. CURRIER, M.D.,
OF NEW YORK CITY.

It is hoped that it will not be considered impertinent to offer a few suggestions upon this subject, apparently so simple, before a body composed so largely of abdominal surgeons, or surgeons who are familiar with abdominal operations, as is this section. The fact has been impressed upon my mind not only by my own experience, but by observation of the work of others, and a search of a considerable portion of the literature of abdominal surgery, that the subject in question has not received the attention which it deserves, and that it is by no means a matter of insignificance. This statement will be the more readily accepted if one remembers that

the essential portion of the omentum (the greater omentum alone is referred to in this paper) consists of peritoneum, and that its function, by virtue of the abundance of fat which forms one of its constituent elements, is of importance, inasmuch as it protects to a greater or less extent, the viscera which lie under it from sudden changes of temperature. Such a covering is therefore of great value in those localities in which climatic changes are not only sudden but severe, and in which one requires all the resources of art as well as nature to preserve the physical equilibrium.

It is therefore desirable in all cases in which the abdominal cavity is exposed that one observe the following propositions with reference to the omentum:

1. It should be preserved as nearly intact as the conditions of each individual case will allow.

2. Great care should be exercised to avoid wounding it in making the abdominal incision, or bruising or lacerating it at subsequent stages of an operation.

3. Badly injured portions should be resected with all due precautions, also such portions as cannot be so replaced as to occupy their original position and perform their normal function.

4. Before closing the abdominal wound it should be carefully and evenly replaced as the natural covering of the intestine.

In the large class of cases in which the lesions demanding surgical interference are located entirely, or to a great extent, in the pelvis, the omentum is very frequently a source of no particular trouble during an operation. If the incision is a short one with its lower limit near the symphysis pubis, and the omentum is not voluminous or adherent it may not be seen at all, and we are conscious of its presence only as it becomes entangled about the fingers when they are passed downward into the pelvis. The operation may be completed and the incision closed without a thought or an intimation of the presence of an omentum.

If an abdominal sponge is used to absorb the leakage from divided vessels and protect the intestines it must not be forgotten that as the sponge presses the latter upward it presses the omentum upward also, and when the sponge is withdrawn the omentum may still remain displaced, or gathered into a lump, or otherwise abnormally disposed so that it can no longer perform its proper function. In all the secondary abdominal sections which I have seen, including one of my own, I have never seen the omentum in its normal position. In my case neglect to properly replace this structure furnished opportunity for adhesion of the intestine to the parietal peritoneum, and so near was it to the incision that it barely escaped injury from the knife. In those cases in which the omentum is normal in

appearance but adherent to the parietal or visceral peritoneum the necessity for careful management must be self-evident. If it has been roughly handled peritonitis with new adhesions will almost certainly result. It must therefore be so evenly and so carefully disposed that if new adhesions are formed they will cause the least possible disturbance to the functional activity of the viscera to which they are attached.

Another class of cases includes those in which the omentum is atrophied or defective.

If the abdominal cavity is encroached upon by a large tumor, whether cystic or solid, the integrity of the omentum and its functional usefulness are generally destroyed. With such growths inflammatory processes are of frequent occurrence and may result in the most intimate adhesive union of the omentum with the peritoneal covering of the tumor. Should the new growth attain a large size and the omentum be imprisoned between it and the abdominal wall, the resulting pressure would cause absorption and disappearance of more or less of the fatty tissue in the omental structure, though the adhesive union of the peritoneal surfaces might continue. Of course it may happen that the omentum will be pushed upward by the advancing tumor, and that disturbances from pressure or inflammation will not be of such a character as to impair its structure. If atrophy have resulted from this or any other cause—by atrophy being meant the condition in which the quantity of omental fat is very small, it is not an indication that the omentum will require less careful treatment; on the contrary it must be handled with the greatest delicacy, and spread over the intestine with great nicety before the abdominal wound is closed, for the frailty of its structure endangers its integrity, and a small rent which might be overlooked might furnish entrance for a loop of intestine with disastrous strangulation as a consequence.

In the removal of large tumors with adherent omentum, conservatism and safety alike demand the free excision of all strips and fragments of the destroyed and useless structure. Too often has it been the method to tear away adherent portions from the tumor, tie their bleeding points, and then drop them, careless as to their arrangement, and forgetful of the fact that attachment to the intestinal may result in such a way as to favor intestine obstruction. A far better plan seems to me to leave no long ends floating about among the intestines, but to cut them off as high up as possible, even if it be necessary to approach the neighborhood of the stomach, then having obtained a straight or nearly straight lower border, to tie all bleeding points and scar the entire edge with the cautery at a low temperature.

Another class of cases, which, however, is a small one, includes those in which the omentum is hypertrophied. Such cases may be very trouble-

some. Not only is the deposit of fat of great thickness, but the structure may extend, like a long apron, deeply into the pelvis. To replace such a structure properly is a very difficult matter unless the abdominal incision has been a very long one, and even then it may not be entirely successful. Such a case recently occurred in my practice. The patient was a young widow, a masseuse by occupation, who was recovering from peritonitis and metritis following a curettement of the uterus, when I was called to see her in consultation. In addition to these inflammatory troubles there was a distinct tumor on either side of the uterus, within the pelvis. The patient was hysterical and a morphine eater, but an abdominal operation did not promise to be extra-formidable or extra-hazardous. The adhesions in the pelvis were readily broken up, an ovarian tumor as large as a hen's egg, with adherent and dilated tube, was removed from the left side, and equally degenerated but not quite so large appendages from the right side. The omentum dipped deeply into the pelvis and particular pains were taken to tuck it carefully and smoothly down. The effort was unsuccessful, for the patient died on the sixth day from septic general peritonitis (though there were also two perforations on the anterior aspect of the descending colon), and the inferior portion of the omentum on the right side was compressed into a mass as large as a child's fist, which was necrotic, evidently from interference with its circulation. I do not know that this was the primary or principal factor in producing the fatal result, but it was a factor and therefore carries a lesson and a warning with it. It would have been better in this case, and the rule would apply in all similar cases, to excise the lowest fourth of the omentum throughout its entire width. The remainder would have furnished ample covering for the intestines, and the bad results from pressure might have been obviated. The case which has been narrated is also illustrative of an accident to which the omentum is susceptible when hypertrophied or when adherent to the parietal peritoneum. In the case in question the omentum was very thick and in contact with but not adherent to the parietal peritoneum. In making the incision the tissues below the recti muscles were cut layer by layer, being made tense by the traction of hæmostatic forceps secured to either side of the wound, and then divided. Such a plan usually enables one to avoid cutting either omentum or intestine, for as soon as the peritoneal cavity is reached the tension of the forceps on either side of the wound draws its edges apart and reveals the space. It failed to do so in this instance and the omentum was incised on the supposition that the præ-peritoneal fat was being cut. Of course the mistake was soon discovered and with it the fact that the omentum was hyper-

trophied not only as to thickness but also as to length. I know of no infallible rule for preventing such accidents. It has never happened to me before and I can conceive of its happening to even the most careful and expert operators.

Wounds of the omentum may become sources of danger from sepsis, peritonitis, or hæmorrhage. In cases in which the omentum has been greatly torn or bruised sepsis and peritonitis are probably more frequent than is generally supposed. Certainly a loosely constructed, freely absorbing, easily degenerating tissue like this offers favorable conditions for serious inflammatory and septic trouble when once an injury has been received. The subject is one which invites pathological investigation in unexplored territory. Hæmorrhage from the omentum may be troublesome, serious or fatal. It is more likely to be venous than arterial, an oozing which may show little tendency to cease. A case of hæmorrhage of this character is reported as recently as May 18, of this year, in the *New York Medical Journal*, and in the practice of so eminent and careful a surgeon as Prof. William T. Bull. Fortunately in this case the bleeding was relieved by means of an iodoform gauze tampon within the abdomen, but such treatment would be ineffective and haphazard in many cases and might do serious damage by pressure upon other structures. Hæmorrhage from the omentum can usually be controlled by ligating the layer vessels, whether veins or arteries, with fine silk and touching all oozing points with the cautery. The latter is more effective than hot water irrigation, especially if trouble is anticipated from many oozing points.

Rents and incisions in the omentum have already been referred to, and the peculiar dangers to which they give rise. Hence they must not be neglected nor slighted whether small or large. They should be carefully and accurately closed with a continuous suture of fine Chinese silk or reliable catgut. It should not be forgotten by the abdominal surgeon that the object of his art is not merely to relieve the present suffering of a patient and remove an existing lesion, but to avoid the induction of other lesions which might be more intolerable than the original one. Unfortunately, such an ideal result is not always possible even to the most skillful or the most cautious, and this fact warrants constant vigilance and unwearying discussion of the subject in all its bearings and possibilities.

IN HONOR OF VIRCHOW.—The freedom of the City of Berlin is to be extended to the eminent pathologist and medical patriarch on his seventieth birthday; and upon the same occasion his portrait will be hung in the Council Chamber.

THE REMOTE EFFECTS OF FŒTAL BRAIN INJURY IN LABOR; OR, WHY WE ARE RIGHT-HANDED.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY F. W. GOODALL, M.D.,
OF BENNINGTON, VT.

We are right-handed because of injury of the motor centres of the right side of the fœtal brain in labor. The manner of receiving this injury, and something of its nature, constitute the subject of this paper.

Some may take exceptions to my premises, and assert that the causes which determine the position of the fœtus "at term," are the primary causes of right-handedness. This I decline to discuss. Much might be said concerning the bones, diameters, planes and outlet of the female pelvis, in introducing my subject. All these points I pass over, and pause only to say that the contour of the parts, or the natural structure and relations of the various bones and organs pertaining to the female pelvis, in connection with the physical character of the fœtus, determines in a mechanical way how it shall present at delivery, and the presentation determines what motor centres, if any, shall be injured; and for the purposes of this paper, I embrace all head presentations under four varieties, which will be briefly defined in passing. I deal only with the first and fourth varieties, as it is only in these presentations that the right side of the head takes the brunt of labor. Largely in consequence of the rectum occupying the notch in the left side of the sacrum, the fœtal head, which is naturally the presenting part, presents, in the great majority of cases, with its long axis in the right oblique diameter, the occiput being directed towards the left acetabulum, and the forehead towards the right sacro-iliac symphysis. From the relative position of the uterus, the pelvic canal, its floor and outlet, taken in connection with this position of the fœtal head, the most advanced point of the head in the progress of delivery is usually somewhere to the right of a line drawn from the nasion (root of the nose) to theinion (base of the external occipital protuberance), and between the anterior and posterior fontanelles, a very important field of motor centres. In this position of the head, which is called in obstetric language the "first position," its long diameter is nearly parallel with the superior plane of the pelvis at the commencement of labor, but there is a very decided lateral obliquity of the head, in consequence of the inclination forwards and downwards of the fundus uteri, the right side of the cranium being considerably lower than the left, and the most depending part of the cranium is the right parietal eminence.

The earlier the examination is made the more decided the above condition will be found; as the head passes the brim of the pelvis and descends into the pelvic cavity, it rotates, and soon its long diameter has become nearly antero-posterior, the occiput being directed forward, and the most dependent point has now become the upper and posterior part of the right parietal bone, and this portion of the head is the part that first escapes from the vulva. The second obstetric position we pass over without notice, as in this position the occiput is towards the right acetabulum, the forehead towards the left sacro-iliac symphysis, and the left parietal eminence is the most advanced point of the head. The third obstetric position, with the forehead opposite the left acetabulum, the vertex towards the right sacro-iliac symphysis, and the left parietal eminence the presenting or most dependent part of the head, we also pass over. In the fourth position, with the forehead directed towards the right acetabulum, and the occiput towards the left sacro-iliac symphysis, we again find the right parietal bone most prominent, but in this presentation it is its anterior and upper part that is first reached by the finger, and injuries received in this position involve the right motor centres, as is also the case in the first presentation.

The relative frequency with which these several presentations are met, vary somewhat as stated by different observers, but it is conceded by all that the first variety by far outnumbers all the others. I think it is perfectly fair to say that from 70 to 75 per cent., or more, of all head presentations, are of the first and fourth varieties; hence 70 per cent. and upwards of all children presenting naturally, are born with the right side of the head subjected to a greater degree of mechanical pressure and violence than is the left side, and it is to this violence or injury of the right side of the fœtal head, that I wish to call your special attention.

It is only necessary to mention the existence of the caput succedaneum, so often seen at birth, that you will at once recognize and concede that the fœtal head has been subjected in some cases to a degree of pressure amounting to violence, varying in different cases, according to the expulsive power, and resistance offered by the parts through which it has passed. This scalp tumor is usually single, but in very protracted cases, especially if of marked severity, we may find two distinct tumors, or even a fairly well defined chain of several small ones, more or less blended in one mass of contusion.

All are not agreed as to the exact manner in which these tumors are produced. I was taught in my student days that they were due to pressure upon a rigid os, but personal observation of the phenomena of labor teaches me that the caput succedaneum is due to a lack of support of that

portion of the head which engages within the ring of the cervix, and later on is found in the vagina with nothing to support it but a species of void, during the pressure of the combined forces brought to bear upon every inch of the remaining superficies of the fœtus. This small unsupported area represents, or is the point of impact, so to speak, of all the tremendous force hurled upon the fœtus as a whole, at every repetition of the labor pains, and in consequence of the varying position of the head, due to rotation, we get a little change in the position of the so-called point of impact, and in protracted, tedious cases, different points of impact remain nearly stationary, long enough to give rise to an individual tumefaction for the varying positions, thus giving rise to one or more tumors, as the case may be. These tumors are frequently serous in character, and are not infrequently filled with blood, as has been too often shown by puncture or otherwise. With such palpable evidence before us, it is not too much to claim that a like effusion may take place within the cranium, and if any one questions the correctness of this deduction, it can easily be sustained by consulting standard works, in which we are taught that hæmorrhage on to the surface of the brain may take place, or into its substance, and I assert, with laceration of the right hemispheres, even to a fatal extent, as one of the accidents incident to labor independent of instrumental assistance or interference—and to these *pathological lesions the physiological condition of right-handedness* is due.

These injuries, varying from the barely perceptible, to the rapidly fatal cases, produce changes in the survivors of like variable extent. The violence giving rise to the effusion of serum or blood within the cranial vault, with or without laceration of brain tissue, is a factor not to be lost sight of, and in connection with the effusions and lacerations we may get circumscribed atrophy of the brain, or modified brain tissue, as a result of secondary inflammatory action, or impaired nutrition, giving rise to permanent, weakened nervous energy, independent of the direct effect of the effusion or laceration, and these injuries may extend deeply, so as to involve not only the centre of speech of the right side, dwarfing it even to a rudimentary condition, but also to the extent of involving the origin of the right cranial nerves, at least those supplying the muscles of mastication, as may be seen by observing that right-handed people, other things being equal, masticate their food on the left side, these muscles being supplied with motor power by the left cranial nerves, which do not decussate as do the spinal nerves. By comparing the caput succedaneum of the infant at birth, with the field of motor centres of Ferrier, it will be seen at a glance, that the centre for the hand, forearm, arm and leg of the left side, are embraced in the field cov-

ered by the several points of impact during labor in the first and fourth obstetric positions; and the effect being somewhat diffused over the surrounding portions of brain tissue, it is not difficult to appreciate the very general remote effect, involving the muscles of the entire left side of the body; a condition of things heretofore never satisfactorily explained, but easily accounted for in this manner, and if no evidence of brain injury existed in these cases, other than the weakened condition of the left side of the body, that of itself would be evidence of such an injury, that cannot be explained so readily in any other manner. Any discrepancy that may exist in the exact location of the different motor centres as given by different observers, for instance, Ferrier and Horsley, is only apparent, not real, as the one locates with sharp limits and closely defined groups of muscles, while the other generalizes in his location of centres, and embraces large areas, or several systems of muscles, in his individual groupings, which, taken as a whole, correspond very closely.

Lectures on Obstetrics, Tyler Smith, p. 342, fig. 107.

- R.—Right parietal bone.
L.—Left parietal bone.
1, 1, 1.—The different points of the right parietal bone which present successively in the first position.
4.—The part of the parietal bone which presents at the os uteri in the fourth position at the commencement of labor.
4 A.—The part of the parietal bone which presents at the os uteri in the fourth position, when the head is delivered in the occipito-posterior position.
4 b, 4 b.—The points of the right parietal bone which present successively when the head, presenting in the fourth position, makes the quarter turn, and is delivered in the occipito-anterior position.

The foregoing is the primary cause of right-handedness, but heredity plays a very important,

secondary part. Upwards of 70 per cent. of all natural presentations, present in a manner which we have seen tends to an injury, which favors atrophy or defective development of the right half of the brain, extending so deeply as to involve not only the centre of speech, but also the origin of the right cranial nerves.

This extreme brain lesion is not claimed for all the large per cent. of children presenting in the first and fourth positions, but it is claimed that a sufficiently large proportion of these cases does suffer as I have indicated, so that when we consider the repetition of the lesion through the thousands of years of human existence, there can be no doubt but what we have all the requirements for hereditary influence, which I consider unessential, however, and yet I consider it as a factor of no mean importance, and to illustrate the power of repetition, I quote Tyler Smith, *Lectures on Obstetrics*, page 318, who says: "The Caribs flattened the foreheads of their children, and the continuance of this practice through succeeding generations produced a natural flattening of the anterior part of the head, until the Carib infants were born with flat heads. Hippocrates gives an account of the Macrocephali, a Scythian race believed to have inhabited the Crimea, of whom the Father of Physic says: 'There is no other race of men which have their heads in the least resembling theirs. At first, usage was the principal cause of the length of their heads, but now nature coöperates with usage. They think those the most noble who have the longest heads. It is thus with regard to the usage: immediately after the child is born, and while its head is still tender, they fashion the head with their hands, and constrain it to assume a lengthened shape, by applying bandages and other suitable contrivances, whereby the spherical form of the head is destroyed, and it is made to increase in length. Thus at first usage operated, so that this constitution was the result of force; but in the course of time it was formed naturally, so that usage had nothing to do with it.'"

I could multiply examples indefinitely, but forbear. My position once being established, all such phenomena as the preponderance of tuberculosis of the left lung, the more frequent appearance of cancer in the left breast, and the oft commented upon, greater frequency of left lateral laceration of the cervix uteri, are at once easily explained, upon the basis of left side weakness, or left side enervation.

THE OLDEST AND LARGEST MEDICAL SOCIETY IN THE UNITED STATES.—The total active membership of the Medical Society of the County of New York is now given at over 1,100. At the last two meetings an increase of over one hundred has developed in the membership.

ADENOMA UTERI.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, at Washington, D. C., May, 1891.

BY HENRY C. COE, M.D.,
OF NEW YORK.

Introduction.—The writer formerly regarded true "malignant adenoma" of the corporeal endometrium as an extremely rare disease; late observation has convinced him that it is more common than he had supposed.

There has been very great confusion in the nomenclature of diseases of the endometrium. Mucous polypi, endometritis fungosa, true adenoma and adeno-carcinoma, have all been described as varieties of adenoma. This is not only anatomically incorrect, but leads to serious error from a clinical standpoint. Even such an acute observer and clear writer as Winckel has introduced confusion into his description of the condition. Many diagnoses are made from a microscopical examination of curettings alone. In doubtful cases, no careful pathologist will positively commit himself on such insufficient evidence. The crucial test of malignancy is *invasion of the submucous layer*; this implies examination of sections of a growth made *in situ*, after removal of the entire uterus. The writer starts out with the proposition that there is only one variety of true adenoma, and that is essentially malignant clinical. So-called "adenomatous polypus," "benignant adenoma" and "endometritis fungosa," are not considered at all, since they are not true adenoma.

Brief Historical Review.—Matthews Duncan is credited with the first reported case of malignant adenoma, though the diagnosis was not supported by a subsequent autopsy. Breisky and Eppinger reported most thoroughly a *bona fide* case in 1877, which has become classical. Schroeder wrote on the subject a few months later, describing two cases, and Veit confirmed his and Breisky's views regarding the ultimate transition of adenoma to adeno-carcinoma. Mann, Bertolet, Thomas and Goodell reported supposed cases, but Mann's description (case of Lusk's) is alone convincing. The most recent communications have been by Ruge, Veit and Fürst, the former having reported a case three years ago. The writer published a communication on the subject two years ago.

The writer has examined uteri removed by Wylie and Bache Emmet, which were undoubted specimens of pure adenoma uteri, that of Wylie's being an exquisite example of the diffuse form. He has himself extirpated two uteri in which the condition was circumscribed adenoma, and one in which there was a transition to adenoma-carcinoma. All five patients made a good recovery.

[Here follow brief histories and descriptions of the writer's specimens, which were to be presented to the Section.]

General deductions from the above cases:

Anatomy.—Unnecessary to describe the ordinary microscopical appearances of adenoma. The important point is that the malignant character of adenoma of the endometrium is shown by the fact that it is not confined to the *mucosa*, but *invades the submucous and muscular layers*. Moreover, in some specimens (as in Breisky's), the transition to carcinoma has been clearly established.

Symptomatology.—There is no clearly defined set of symptoms peculiar to adenoma, but the writer does not agree with Ruge that they are never distinguishable from those of carcinoma corporis uteri. In the first place, the symptoms of adenoma are of longer standing than are those of primary carcinoma. There is less pain, the hæmorrhages are less frequent and profuse, and, so far as the writer's observation has extended, there is little or no foul-smelling, watery discharge. Glandular and perimetric involvement has been entirely absent in the four cases personally observed by the writer. The negative results of the examination of curettings is important, since there is seldom doubt in a well-marked case of carcinoma.

Diagnosis.—This is sometimes extremely difficult, yet it is of more importance from a scientific than from a surgical standpoint. Given a patient who has passed the menopause, and who has for several months had slight atypical hæmorrhages with lancinating pelvic pains, even if a foul discharge, cachexia and other characteristic symptoms be wanting, we should make a thorough examination of the interior of the uterus by means of the finger and curette, after dilatation with tents. Finding a localized or diffuse papillary growth, we are justified in removing the uterus without delay, even if the microscope shows no positive evidence of malignant disease.

Prognosis.—As the history of the few *authentic* cases of adenoma uteri has shown, the course of the disease is exceedingly slow and insidious. It is the least malignant of all the forms of malignant disease of the endometrium, but if left to itself, it inevitably assumes a more fatal form. We should not be misled by the long-continued good health of the patient, and the absence of profuse hæmorrhage, offensive discharges, and local pain and tenderness. The end, though long delayed, is certain.

Treatment.—Total extirpation of the uterus is the only treatment to be considered. Frequent ennetting simply hastens the transition to the more malignant type of which adenoma is the initial stage. The patient is relieved for a time, but her symptoms soon reappear in an aggravated form. The use of the galvano-cantery, though more efficient, is no less objectionable. Remove the entire uterus. In cases of adenoma the operation is easy and uncomplicated, and there is a better prospect of a radical cure than in carcinoma, either of the cervix or corpus uteri.

Summary.—"Benignant adenoma" is a misnomer. There is only one variety of true adenoma of the corpus uteri, and that is both clinically and anatomically malignant.

Adenoma uteri is not, at the outset, identical with adeno-carcinoma, but is to be regarded as the initial stage of the latter. Its malignancy is shown by its early recurrence after removal with the sharp curette.

The symptoms of adenoma are less clearly defined than those of carcinoma, being usually slight irregular hæmorrhages, and pelvic pains extending over a long period, without cachexia and offensive discharges.

Palliative treatment is worse than useless. Total extirpation promises a radical cure if performed early, or during the pre-cancerous stage.

LAPAROTOMY WITH REPORT OF CASES.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 1891.

BY J. H. BRANHAM, M.D.,

OF BALTIMORE, MD.

The following paper is a report of the eleven laparotomies which I have done up to this time. They have all occurred during the past two years. The number is too small to be of much value from a statistical standpoint, but the difficulties met with in these cases are probably more keenly appreciated by a beginner than by an older operator, and I hope, by calling your attention to these, to make my report of value to those surgeons who are entering this field.

could not be found. The bladder, which was adherent to the anterior part of the tumor, was drawn nearly up to the umbilicus, and was opened during the operation. It was carefully closed, and the patient made an uninterrupted recovery.

Case 2.—The right ovary was displaced into the inguinal region, was enlarged, softened, beginning to suppurate, and attached to the lower part of the small intestines by recent adhesions. In separating these, about one inch of the longitudinal diameter and more than half of the circumference of the gut was denuded of peritoneal covering and looked very dark, but this did not prevent a rapid convalescence.

Case 3.—Patient had suffered for thirteen years with symptoms of pelvic inflammation accompanied by dysmenorrhœa, fainting spells, etc. She had been confined to bed for months at a time, and was constantly in pain. The ovaries were atrophied and surrounded by many adhesions, and were enucleated with much difficulty. The wound healed by first intention, and although the patient has since continued to menstruate slightly her general health is much improved, and she suffers very little pelvic pain.

Case 4.—This patient was a robust German woman, who, in addition to immense abscesses of both tubes and ovaries had a large abscess between the uterus and vagina in front and the rectum behind. In attempting to enucleate this several of the large pelvic veins were torn, and it was necessary to pack the pelvis with antiseptic gauze to control the hæmorrhage. The post-mortem showed that the abscess behind the

8	Oct. 13.	Agnes L.	White.	26	M	1	Double abscess of tubes and ovaries.	Both tubes and ovaries removed.	Yes.	Recovery.
9	Nov. 13, 1890.	Catherine K.	White.	30	M	5	Left pyosalpinx and ovarian abscess. Right hydrosalpinx.	Both ovaries and tubes removed.	Yes.	Recovery.
10	Feb. 10, 1891.	Jane R.	Col.	37	M		Ventral hernia following laparotomy.	Omentum separated from sac, edges of peritoneum freshened and sutured.	No.	Recovery.
11	March 21, 1891.	Mary W.	White.	33	M	4	Right ovary displaced. Both ovaries fibroid and excessively tender.	Both ovaries and tubes removed.	No.	Recovery.

I will give, first, a tabulated history of the cases and then will call your attention to those points which seem to me to be of most interest.

Case 1.—Operated with intention of removing ovaries and tubes, but the tumor in its growth had surrounded them to such an extent that they

uterus could not have been enucleated without fatal result, and simple drainage would have been better.

Case 5.—Was a large pyosalpinx. Recovery rapid, and the patient is in excellent health at the present time.

Case 6.—Patient was nearly three months pregnant, which condition was suspected before the operation, but as the symptoms pointed strongly to pyosalpinx it was deemed best not to wait. The entire uterus was soft and cyst-like. The upper part as much so as the lower, which seems to be contrary to the opinion of Hager as indicated by the descriptions of his sign of pregnancy which I have seen.

The pregnancy was not interrupted and terminated normally about six months after operation. Since delivery she is said to have developed a slight hernia.

Case 7.—This case was operated on for menorrhœa, which prevented the patient from earning her living. All other methods of treatment had been tried without avail. The uterus, which was retroverted, was stitched to the abdominal wall. The patient was out of bed the night after the operation and walked the second night; notwithstanding, she recovered without fever, but developed an abdominal hernia which has since been cured by Prof. Thos. Opie.

Case 8.—Recovery uneventful except symptoms of impaction of the bowels caused by the use of morphia, and milk diet.

The use of morphia was necessary as the patient could not have a trained nurse. She is in excellent health at this time.

Case 9.—Patient had been suffering with symptoms of pelvic suppuration for nearly two years. On the right side the hydrosalpinx was attached to the broad ligament and uterus by a thick vascular pedicle in which the vessels were distended and softened, and severe hæmorrhage occurred at the time of the operation. The ligatures, which were first applied to the pedicle in the usual way, and, afterwards, to the vessels themselves, cut through, and the bleeding could only be partly arrested. Oozing continued for thirty hours, shortly after which the drainage tube was removed.

The wound suppurated and the patient was in a precarious condition for three weeks, after which she slowly improved. I was called to see her in March, and found her suffering from acute nephritis with general œdema and ascites. Under suitable treatment the albumen has disappeared from the urine and the dropsical symptoms have subsided, but she is left with a tendency to abdominal hernia.

Case 10.—The hernia here was large; the coverings consisted of the skin and superficial fascia, all the other structure being separated. The inner wall was lined with omentum which was closely adherent throughout its entire extent, and was separated with great difficulty. Since operation there has been no tendency to return.

Case 11.—Here the reflex symptoms had been very severe. Very much of her time was spent in bed and her pain was excessive. Dysmenorrhœa

and menorrhagia very great, which kept her reduced to a skeleton. Her right kidney is very movable and at times is tender. This movability, which is shared by the left to a great extent, I think is partly explained by absolute absorption of all the abdominal fat. The time is too short to judge as to the final result in this case, but the improvement to date has been marked.

Cases 1, 2, 4, 5, 6 and 7 were done in the public ward of the City Hospital of Baltimore. Case 11 was done in private room of same hospital. Case 10, public ward, Bay View Hospital. Cases 3, 8 and 9 were performed at the homes of the patients. The strictest antisepsis was observed in each operation. Drainage was accomplished by the open glass tube plugged with antiseptic cotton, the fluid being removed by an ordinary glass or rubber syringe, to which was attached a piece of soft rubber tubing.

Cases 2, 4, 5, 8 and 9 were operated on for pelvic suppuration. Results in 2, 5 and 8 were all that could be desired; case 4 died, being the only fatal result. Tendency to ventral hernia noted in cases 6, 7 and 9 was undoubtedly caused in the first by distention of the abdomen in the progress of pregnancy.

In case 6, by the unruliness of the patient, who, when not watched closely, would get out of bed, and thus dragged the sutures, which were attached to the uterine, into the abdomen, from whence they were removed with great difficulty.

In case 9, it was caused by the distention of the abdomen due to the ascites. In cases 3, 7 and 11 the operation was done to cause premature menopause. In case 3 this was not accomplished. The patient still menstruates slightly and at irregular intervals. Here the ovaries were imbedded in old adhesions, and it is quite possible that in enucleating them a small amount of stroma was left which would account for the incomplete success. In the other cases the menstruation was arrested at once.

In these cases where I have operated to bring about the menopause the patients have been hopeless invalids, all other methods having failed to relieve them.

They thoroughly understood the effects of the operations and were anxious to have it done.

I have refused to operate in a number of cases where the symptoms were not so severe as to make life unbearable.

COPPER IN CHLOROSIS.—Liégeois has obtained very satisfactory results in chlorosis from the following formula, suggested by Luton:

R. Cupri acetatis neut., gr. 16.
Sodii phosphat. cryst., gr. 34.
Pulv. glycyrrhizæ, aa q. s.
Glycerinæ, aa q. s. ʒj.

Ft. pil. no. j.

One or two pills before eating, noon and night.

THE ETIOLOGY OF DIPHTHERIA.

Read in the Section of Practice of Medicine and Physiology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 5-8, 1891.

BY J. LEWIS SMITH, M.D.,
OF NEW YORK CITY.

No other infectious disease of childhood has been so much investigated in recent years as diphtheria. It has been the subject of full and accurate study by the most distinguished clinical instructors in both hemispheres, and numerous microscopic examinations and experiments with cultures of its specific principle have thrown light on its nature. Nevertheless, it has continued to extend and destroy its victims. It has encircled the globe, occurring with a heavy mortality in every country reached by commerce or travel. We read in medical journals of its prevalence, with the usual death rate, in Brazil, Algiers, and in distant Australia. It has occurred for ages in Eastern Asia, where it probably originated, and the complex prescriptions of the Chinese doctors, which have descended as an inheritance with little variation from their ancestors, and which are frequently employed by European residents of China, have lately been added to the literature of this disease.

Notwithstanding the many discussions of the treatment of diphtheria in medical societies, the many remedies which have been employed, and the additional light thrown upon its nature by the discovery of its cause, the percentage of deaths from this disease continues large. A recent French writer on diphtheria states that the deaths in France are in numerical excess of the births, and largely on account of the prevalence of this disease. In London the mortality from diphtheria has been steadily increasing. Within the metropolitan registration area it caused 952 deaths in 1887, 1,311 deaths in 1888, and 1,588 deaths in 1889. These numbers would be greatly increased if the deaths reported from croup, which, wherever diphtheria is prevailing, is known to be, with few exceptions, a manifestation of this disease, were added to them. (*London Lancet*, May 17, 1890.) In New York City the deaths from diphtheria were 1,914, and from croup 639, aggregate 2,553 in 1888; from diphtheria 1,686, and from croup 605, aggregate 2,291 in 1889. In Brooklyn the deaths from diphtheria were 984, and from croup 391 in 1889; from diphtheria 1,101, and from croup 366 in 1890. These are probably the average statistics of the mortality from diphtheria in the cities where it prevails.

The presence of a great evil always leads to strenuous efforts to determine the exact nature and the most effectual mode of combatting it. It is now known that diphtheria is produced by a linear or rod-shape microorganism, having about the length of the one which causes tuber-

culosis, but considerably thicker. A rod-shape microbe is termed a bacillus, and that which causes diphtheria, is designated the Klebs-Löffler bacillus in honor of Klebs, who announced his discovery of it in 1883, and of Löffler, who subsequently more thoroughly investigated its nature. Löffler cultivated it in appropriate media, and after a succession of cultivations, which removed it several generations from its source in the child, inoculated pigeons, rabbits and guinea pigs, with the last culture, and produced in them typical diphtheritic inflammation. Many others have repeated and varied these experiments with results similar to those obtained by Löffler, so that the theory that diphtheria is caused by the Klebs-Löffler bacillus is accepted. This bacillus presents aspects which to the experienced eye are characteristic. It often has a granular appearance and is stained in two minutes by the violet of methyle; it often exhibits a more intense coloration of its extremities than of its central parts, and its extremities are sometimes swollen so as to present a dumb bell appearance, or only one extremity is swollen, so that it has the shape of a pear or gourd; occasionally it is curved like an arc. (*Le Bulletin Med.*, June 15, 1890.)

The Klebs-Löffler bacillus alighting upon the faucial or other mucous surface, or the skin denuded of its epidermis, obtains a nidus favorable for its development and propagation, but it does not enter the interior of the system; it is not taken up by the lymph ducts or blood vessels and conveyed to the internal organs; it remains localized upon the surface and produces there the characteristic inflammation; acting solely upon superficial parts, it cannot in itself produce systemic infection, or blood-poisoning, but like as the venomous reptile or the bee secretes its poison, which it communicates by its fang or its sting, it produces a chemical poison, which is readily taken up by the vessels and conveyed to the internal and vital organs.

This substance, which is the poisonous agent in diphtheria, and which produces systemic infection and death of the multitudes who perish from diphtheritic blood-poisoning, has been carefully examined and experimented with by L. Brieger and K. Fraenkel (*Berliner Klinische Wochen.*, March 17th and 24th, 1890). They say that it may be evaporated at 122°, but is destroyed by a heat above 140°. It is soluble in water, but is insoluble in alcohol. It is not precipitated by ebullition, nor by the following medicinal agents: sulphate of sodium, sulphate of magnesium, chloride of sodium, nitric acid and acetate of lead. On the other hand, it is precipitated by concentrated carbonic acid, the ferro-cyanide of potassium, acetic acid, carbolic acid and nitrate of silver. It has, say Brieger and Fraenkel, the following composition: Carbon, 45.35; hydro-

gen, 7.13; azote, 16.33; sulphur, 1.39; oxygen, 29.80.

When it was separated from the bacillus by passing through the porcelain filter, and inoculated in rabbits and guinea pigs, it caused death in the small quantity of two and a half milligrams to each kilogram in the weight of the animal. Sometimes death did not occur until after weeks or months, while the bacillus itself inoculated upon one of the surfaces, caused inflammation with the exudation of fibrin, producing the diphtheritic pseudo-membrane, this chemical product of the bacillus, freed from the bacillus by the filter, did not, when inoculated, cause any fibrinous exudation or diphtheritic pellicle, though its action was so highly poisonous. According to Brieger and Fraenkel it is allied in its composition to the proteids or albuminoids, and it bears considerable resemblance to ichthyotoxinon, the poison secreted by sea eels. Many years ago Trousseau noticed this resemblance and related an instance in which seamen became paralyzed, some of them for three months, by eating a cooked eel. He saw the resemblance in these cases to diphtheritic paralysis. In a vacuum the poison produced by the Klebs-Löffler bacillus retains its virulence for weeks or months. MM. Roux and Yersin state in the records of the Pasteur Institute, Paris, that their investigations have strengthened the belief that the Klebs-Löffler bacillus is in itself comparatively innocuous, the chemical substance produced by it, described above, being the poisonous principle. These bacteriologists also separated this substance from the bacillus by filtration through a porcelain filter, and by inoculating dogs and sheep with it, produced in them a paralysis apparently identical with that occurring in children from diphtheria. Roux and Yersin also state that while the filtered liquid freed from the bacillus, and containing only the chemical substance, if infected under the skin of rabbits and guinea pigs, was very fatal, it caused little inconvenience, if introduced into the stomach.

Experiments similar to those related above, and clinical observations confirmatory of the views expressed by Klebs-Löffler, Roux and Yersin, have been made by many others, which, since they are in the main corroborative, need not be related here.

Pseudo-diphtheria.—This term is employed through want of a better one. It is proper to state in this connection that clinical observations and experiments, carefully made, have demonstrated the fact that certain other microbes besides the Klebs-Löffler bacillus, sometimes produce a pseudo-membranous inflammation upon the faucial or other surface, which as regards its anatomical characters, appears to be identical with that in true diphtheria. The only differ-

ence thus far discovered has been the absence of the Klebs-Löffler bacillus, and the presence of other microbes. Whether these other microbes produce poisonous albuminoids by which the system becomes infected must be determined by future research, but if they do, these products seem to be different from that generated by the Klebs-Löffler bacillus, for the peculiar paralysis which is so common in true diphtheria does not appear to occur, or is infrequent in pseudo-diphtheria. If the systemic infection be different in true diphtheria and pseudo-diphtheria, as appears to be the case, we see the propriety of recognizing two distinct diseases, just as our ancestors differentiated measles and scarlet fever, which, since both had a cutaneous efflorescence and redness of the fauces, were formerly considered identical.

M. Talamon states that not only other microbes, besides the Klebs-Löffler bacillus, but also certain irritating medicinal and chemical agents, have the power to excite an inflammation with fibrinous exudation upon the faucial, or other surface, to which they are applied, which cannot be distinguished by its appearance and anatomical characters from that of true diphtheria except by the absence of the cause of the latter disease, to wit, the Klebs-Löffler bacillus. The inflammation produced by non-microbial irritating agents, as steam, boiling water, chlorine, cantharides, and ammonia, though attended by an exudation of fibrin, is obviously entirely distinct in nature, from that caused by microbial agency. Like any inflammation from traumatism, it always remains a local disease, and must not be confounded with diphtheria or pseudo-diphtheria.

Pseudo-diphtheria, according to my observations in the institutions and in family practice, occurs most frequently in the course of the eruptive fevers, and especially in scarlet fever. We must not mistake the necrosis or gangrene which is not uncommon upon the swollen fauces, in severe anginose scarlet fever, for a fibrinous exudation. It is difficult, perhaps in some cases impossible, to distinguish the one from the other on inspecting the fauces. Necrosis occurs upon the most swollen part, as over the tonsils or in their vicinity. A fibrinous exudation due to microbial agency is likely to extend to the velum or uvula. Diphtheria or pseudo-diphtheria complicating scarlet fever usually occurs when there is not sufficient tunefaction to cause necrosis, but it may supervene upon, and complicate a necrosis.

M. Sevestre, of Paris, says that the pseudo-membranous sore-throat, which occasionally occurs in scarlet fever, is generally considered in France as having a diphtheritic origin, and patients who are suffering from it are placed in the diphtheritic ward. It is, however, says he, a variety of sore throat, which ought to be dis-

tinguished from the diphtheritic. It is an early manifestation developing in the first days of scarlet fever. It is characterized by the production of white patches, which frequently are exactly similar to those of diphtheria, and which may occur upon the uvula and soft palate, so that its diagnosis from diphtheritic inflammation is often very difficult, but the pseudo-membrane does not extend to the larynx, and the general condition of the patients remains, in most cases, satisfactory. These sore-throats, adds Sevestre, commonly end in recovery, and they do not communicate diphtheria to neighboring children. Some of the patients alluded to by Sevestre, evidently had what we have designated pseudo-diphtheria, an inflammation with fibrinous exudation produced by other microbes than the Klebs-Löffler bacillus, probably mainly by cocci, which are found in abundance in these cases. Some of the patients referred to by Sevestre, perhaps had scarlatinal necrosis. MM. Wartz and Bourges made microscopic examinations in nine cases of supposed diphtheria, complicating scarlet fever. In two of the cases in which the pseudo-membranous inflammation occurred at a late stage of scarlet fever, the Klebs-Löffler bacillus was found in the exudate, but in the other cases, in which the pseudo-membrane appeared early, this bacillus was not present, but streptococci were abundant. In six of the cases the pyogenic staphylococcus was also observed (*Arch. de Med.*, May, 1890). The fact that the Klebs-Löffler bacillus did not occur in cases in which a pseudo-membranous exudate appeared at an early stage of scarlet fever, justifies the belief, the writers say, that the appearance upon the faucial surface, which so closely resembled that in diphtheria, was due to the intensity of the scarlatinal inflammation. But in the two cases, in which the pseudo-membrane appeared at an advanced stage (the sixth and ninth days), the Klebs-Löffler bacillus was present, and it is evident that true diphtheria had supervened.

We might quote the observations of Prof. Hensch, of Berlin, and Dr. McWerney, of the Royal Academy of Medicine of Ireland, showing that in scarlet fever the faucial inflammation, accompanied by the formation of a pellicle, so closely resembles that of diphtheria that it is difficult to make the differential diagnosis. But this inflammation is not followed by paralysis except when true diphtheria supervenes. It is caused by the agency of the scarlatinal, and other microbes than the Klebs-Löffler bacillus.

The *American Journal of Medical Sciences* for May, 1889, contains an elaborate paper by Prof. T. M. Prudden, relating the microscopic examinations of the pseudo-membrane underlying tissues and the viscera, removed from the bodies of 24 children, who were supposed to have perished from diphtheria. But these cases, with two

exceptions, were treated in institutions, where epidemics of the other infectious diseases are frequent, and sixteen of them had scarlet fever, measles, whooping cough, or an erysipelatosus or phlegmonous inflammation, in parts at a distance from the fauces at the time of death. In no one of these specimens sent to Dr. Prudden by curators or reputable physicians, in the belief that they were removed from the bodies of those who had died of true diphtheria, could he find the Klebs-Löffler bacillus, but instead he discovered the streptococcus and staphylococcus. These specimens for a time misled Dr. Prudden and the entire medical profession in this country, for the absence of the Klebs-Löffler bacillus in the specimens of twenty-four consecutive cases seemed to show that this bacillus could not be the cause of diphtheria. But in no one of these cases so far as their histories show, did paralysis, which is so characteristic of true diphtheria, occur. These twenty-four patients died from a disease produced by the agency of other microbes than the Klebs-Löffler bacillus, or what we, through want of a better term, have designated pseudo-diphtheria. Prof. Prudden has since discovered the Klebs-Löffler bacillus in a dozen or more cases of true diphtheria. Prof. Welch, of Johns Hopkins University, also finds the Klebs-Löffler bacillus in diphtheria, has obtained cultures of it, and by inoculating animals with these cultures has apparently produced the genuine disease in them; therefore he believes that the theory that this organism causes diphtheria is fully established.

From the facts as stated above we repeat that the disease heretofore designated diphtheria we must now regard as two diseases, to wit: diphtheria resulting from the action of the Klebs-Löffler bacillus, and pseudo-diphtheria, resulting from the agency of other microbes, or else we must recognize two varieties, or rather forms, of diphtheria, the one caused by the Klebs-Löffler bacillus and the other by other microbes. I may add that there is no evidence, so far as I have been able to ascertain, that the poisonous albuminoid generated by the Klebs-Löffler bacillus, which albuminoid causes the systemic affection, or blood-poisoning in true diphtheria, is produced by any other microbe. If the streptococcus, staphylococcus or any other form of coccus produces a poisonous albuminoid similar to that generated by the Klebs-Löffler bacillus, I am not aware that it has been discovered or isolated.

In the light of our present knowledge are we able to state whether diphtheria is primarily a local or primarily a constitutional disease? It seems that we must regard the disease produced by the Klebs-Löffler bacillus as primarily local; but in reference to the disease produced by other microbes the question is still an open one, for in fatal cases the micrococcus is found in internal organs, as well as at the seat of the inflammation

upon the mucous surface. The length of this paper prevents our discussing the very important subject of the modes of propagation of diphtheria, which must be reserved for some other occasion.

PREMENSTRUAL PAIN AND CONVOLUTED TUBES.

BY FRED B. ROBINSON, B. S., M.D.,

OF TOLEDO, OHIO.

PROF. OF ANATOMY AND CLINICAL SURGERY TOLEDO MEDICAL COLLEGE.

The views in this article occurred to me from the examination of about 700 ova ducts of man, cow, pig, sheep and dog. The substance of the views is that the main premenstrual pain and the pain which women have who are afflicted with tubal disease is essentially due to peristalsis or vermicular motion of the tubes themselves. It is, in short, tubal colic. The method of arriving at this idea was the following:

Four years ago I wished to acquire a practical knowledge of the heart and its diseases, so I dissected and examined a large number of the hearts of all animals within range of acquisition. Considerable vivisection was done. It does not require but few vivisections to demonstrate that the essential motive power of the heart is situated in its base. That the main ganglia which control and initiate regular movements to the heart reside in the auricles and not the ventricles. The nerve ganglia which give the heart its *rhythm* belong to its basal portion. These ganglia are called Remak's, Ludwig's, Bidder's and Schmidt's, and are well termed automatic cardiac ganglia. It is easy to observe the heart die out from apex to base. If the vivisection is carefully done the auricles (in the dog) will beat regular considerable time after the ventricles have ceased their rhythmical action, so I saw that the heart (which is one of the viscera) had some nerve apparatus within itself which gave it a rhythmical, periodical, cyclical motion. The heart waxed to a maximum and waned to a minimum in its continual motion. In short, it exploded about 75 times a minute.

Three years ago I wished to acquire a similar practical knowledge of the intestines and their pathology. So we included in the examination and dissection the above mentioned animals, but especially the dog, on which the main vivisection was done. To demonstrate the point, the dogs were chloroformed and the abdomen opened. The intestines were generally found still and quietly at rest until the exposure to air stimulated them to move slightly. The dog was nearly always chloroformed to death inside of twenty minutes. But after the dog was dead the intestines, by simply tapping them, would go through their peristalsis, their vericula, periodical *rhythmical*

cal motion for at least an hour. If the temperature was 80 degrees the cyclical movements could be kept up an hour and a half. In such experiments alone can be realized what is known as the "invagination of death." Now the same phenomenon which was seen in the action of the heart, is again witnessed in the intestines. It is *rhythmical* motion and must be caused by the same kind of an apparatus known as a ganglion. In fact the ganglia which do the motive work of the intestines are situated in the plexus of Auerbach and the plexus of Meissner. These plexuses reside in the gut wall. The same form of work can be done with the kidney and bladder and the same kind of ganglia found. They are *rhythmical* ganglia. It may be remembered that a nerve ganglion is a little brain. It is an automatic center. It is a sensorium of independent action. A ganglion is possessed with the powers of secretion and nutrition. It is a physiological center endowed with plenipotentiary power to initiate, continue and prohibit action. The function of a ganglion is to produce a rhythm. It is a nerve apparatus which wanes and waxes and explodes. It lives a periodic, cyclical life and the circle of its action is defined by its maximum and minimum points—in time.

Now, this same kind of experimental work was applied to the Fallopian tubes of man, cow, dog, sheep, and pigs. Many hundred ova ducts of the higher animals were carefully examined and lately, while studying with Mr. Lawson Tait, I have had plenty of opportunity to confirm the experiments on fresh human tubes, a few minutes after Mr. Tait had removed them from the patient. Some of the tubes were absolutely healthy, as they were removed for bleeding myoma and other causes. It may be remarked that the Fallopian tubes do not differ from other hollow viscera. They are governed by similar nervous apparatus. The tubes live a rhythmical life. They have a periodic function, and while useful to woman go through cyclical action. After considerable investigation and microscopical work I came to the conclusion that the tubes (and uterus) were governed in their rhythm by ganglia situated along their walls, and along the blood vessels which supply them. In order that these ganglia should be appropriately named, I styled them *automatic menstrual ganglia*.

Until some two years ago, when I began to investigate this subject, I had no idea of the importance of the tubes in the process of menstruation. But now I am becoming convinced that the tubes overshadow every other organ in menstruation. It seems to me that menstruation starts in the tubes and begins with tubal motion. The girl's puberty is heralded by tubal activity, and she is a woman when her tubes begin to move. (I am unable to find any difference in the ovaries at puberty except increased vascularity, and hence

a hastening in maturation of ova). The importance of the tubes in menstruation is best impressed on the mind when we consider their object. The whole business of a tube is to transport an ovum into the uterus from the ovary. As ovulation is a constant and progressive process, it has no periodicity to it. Ovulation has no monthly *rhythm*. An ovum simply bursts when it matures and we do not yet know the life and duration of a graafian follicle.

But menstruation is periodic and *rhythmic*. It is not strange that the essential change in menstruation should occur in the organ most concerned in the process—the tube. The tube must be prepared before it can either secure an ovum or transmit it along its canal. A still, dry contracted tube has really poor facilities for transporting an egg down to the uterus. But wait and observe the tubes awhile before menstruation. The automatic menstrual ganglia become active. As these ganglia approach and wax to a maximum the blood vessels of the tube gradually increase in size. The walls of the tube grow redder and redder until at the climax of menstruation, the tubal vessels are so full of blood that they present a dusky blue color. Step by step as the vessels dilate the automatic menstrual ganglia impart to the tube a vermicular motion, a peristaltic action, especially toward the fimbriated extremity, and this fringed funnel is drawn towards the ovary by the shortening of the muscle which holds the ovary to the fimbria of the tube. The mouth will then drop over the ovary and secure any ovum that may *accidentally* be ripe. At the same time that the tubes become vermicular in motion and the blood vessels dilate and exudation of fluid takes place in the tube which serve as a medium to float the egg down its channel. Hence the automatic menstrual ganglia prepare the tube to float an egg through its channel by giving the tube a vermicular or peristaltic motion, by enticing excessive blood in its vessels, and by inducing exudation of fluid in the tube to serve as a floating medium. Therefore the tubes are not mere ornaments of curiosity but the central organ of menstruation. If a fresh, healthy tube just removed from a woman be squeezed between the finger and thumb at some point, a distinct circular structure will slowly but *rhythmically* follow. At the same time the longitudinal muscular layer will contract and bulge up on each side of the circular structure. Both muscular layers of the tube will act in precisely the same manner as those of an intestine under similar circumstances. This point can be easily verified by watching the end of the Fallopian tube when it is amputated from the uterus. The longitudinal muscular layer of the tube will by contraction draw its fibres away from the end while the circular muscular fibers will constrict themselves into a distinct cone—a point which aids in

recognizing the tube. This vermicular or peristaltic action of the tubes will continue under blood temperature for some half hour if one applies irritation. Hence after an observation of a large number of fresh tubes from healthy animals and also an opportunity to observe the tubes fresh from women in the operations of various surgeons, and particularly in Mr. Lawson Tait's practice, I am more and more, the past few years, convinced of the dominant influence of the tubes in starting and maintaining menstruation. That the tubes properly prepare themselves for the only object of menstruation which is to get an ovum from the ovary to the uterus. The menstrual process, or in other words, tubal motion is initiated, maintained and concluded by the machinery which I have termed automatic menstrual ganglia. But what has all this to do with premenstrual pain and convoluted or contorted tubes? If we know the structure and function, the pathology is clearer. For some time I have observed that many diseased tubes had a spiral or corkscrew shape. In one particular case of removal of the tubes of an infantile uterus, the tube was less than three inches long, but was exactly in the shape of a cork screw. It had an angular, spiral twist. This tube was from a woman who never had a child or conception. The tube was, so far as I could see, absolutely healthy. It had the longitudinal and circular muscular layers healthy, as well as its mucous membrane and ciliated epithelium. Whence came the contortion or spiral bending? I noticed in the young of animals before birth, and for some time after, that the ova ducts are curled and spiral. As time goes on the tubes gradually straighten out toward their functional period. Now, the same spiral bending is observed in human foetal life, and for some time after approaching puberty or tubal motion. So we may say that the spiral, contorted tube is a relic of foetal and early life. In cases of infantile uterus the tubes occasionally retain the foetal condition in some degree. But how are we to account for most diseased tubes being contorted, because most of the diseased tubes belong to women who have had children. Of course these tubes have been once straightened out, for they performed the motion by which an egg floated into the uterus and developed into an ovum.

It is likely that the main idea is atavism, a reversion of type to foetal state. But I notice that the spiral of the foetal tube is regular, while the spiral of the diseased tube is sometimes very irregular. If one will measure the Fallopian tube at the end of pregnancy it will be found lengthened almost twice as long as when in the non-pregnant state. This means that the individual muscles, the external longitudinal layer, are hypertrophied to nearly their ordinary length. But the calibre of the tube or its lumen is not

very much enlarged. This means that the circular or internal muscular layer of the tube does not hypertrophy very much. Hence, the external longitudinal muscular layer hypertrophies with the uterus during pregnancy. This hypertrophy requires a return to normal. It demands involution.

Now, if this involution goes on in an *irregular* manner, the tubal reduction will be uneven, and in this way the tube will become contorted. It is well to remember that the broad ligament or peritoneal covering of the tube does not hinder the tube from becoming contorted but very slightly, unless there has been inflammation of the peritoneum covering the tube. The tube lies loosely, in connective tissue, between the broad ligament, so that it will glide about between the finger and thumb if compressed. The peritoneum can easily be stripped off of the tube. Another remarkable fact I noted with some surprise, was that the peritoneum around the tube did not dip down in the depressions between the angles or bends of the tube, but stretched across them like a diaphragm. In cases of tubal removals for infantile uterus this is occasionally quite noticeable. The tube will lie curled up between the broad ligament like a cork screw with some degree of a regular spiral. However, in multipara the tubes which become contorted have not such a uniform regular spiral bending as nullipara, but present a sacculated bulging at the angles of the bends not unlike a distended intestine. The calibre or lumen of diseased tubes, becomes irregularly dilated, and the irregular dilatation nearly always occurs toward the fimbriated end. The application of these observations becomes reasonable and useful. The tubes are just like any other hollow viscera. They are provided with a nervous apparatus to induce motion or peristalsis. The tubes seem to have an inherent tendency to revert to fetal type or to a spiral condition.

Hence, when any inflammatory disease begins in the mucous membrane, the tendency is to show pathological changes at the fimbriated end first. This irritative condition of the fimbriated end sooner or later occludes the tube by blocking up the lumen with adhesions or inflammatory products. The uterine end is not often occluded in fact, but becomes impassable to fluids by the excessive swelling and angular bendings of the mucous membrane at that point. Now, we have fluids really confined in the tube. Inflammations and adhesions have stopped up the fimbriated end, and swollen mucous membrane has blocked up the uterine end. Under natural and diseased conditions the secretions of the tube accumulate. Hence arises the excessive and painful vermicular or peristaltic motion of the tube, from irritation of the diseased secretions on the automatic menstrual ganglia that control its action. This vermicular or peristaltic motion is tubal colic.

Tubal colic is premenstrual pain. It is pathognomonic of tubal disease. When the intestines have wind or offending material in them, they become occasionally violent in peristaltic movements in order to expel the material (colic). The tubes do precisely the same thing to get rid of their irritating secretions. When both ends of the tubes are closed the peristalsis may become violent, and then the tubal colic is intensely painful and sickening. The ganglionic nature of tubal motion and colic is seen in various cases. The other day I examined a woman who had tubal disease of long duration. She was examined very gently, but the irritation of the examination brought on tubal peristalsis, and of course tubal colic. I carefully inquired of her how long the pain would last from the examination. Her own statement was, when it was once started, it lasted almost *two hours*.

Now, the violent peristalsis of the tubes on the *confined* fluids is what causes the dilatation and thinning of the walls. The greatest dilatation of the tubal wall will be at the bends or angles, which will be the points where the expanding force is the most active. In general, this occurs at the abdominal end of the tube. Considerable observation of the fact that, from those women who suffered long with tubal colic, the operation generally produced the convoluted or contorted Fallopian tube, convinced me that convoluted tubes is a frequent occurrence. The pain that these convoluted tubes give rise to from peristalsis, is what induces the woman to seek aid in her distress. I shall venture a step farther, and say that premenstrual pain is nearly always tubal, and that the gynecologists whom I have heard instruct with such confidence and authority that premenstrual pain was from the uterus, will have to draw their views more to the horns of the uterus, if they want their assertions to agree with facts. It is not to be wondered at that walking or movement induces violent tubal peristalsis and consequent tubal colic in a tube filled and occluded with stinking pus. These women know that rest is the only thing that stops their hopeless tubal pain. To irritate the automatic menstrual ganglia into action in a pus tube, is generally a half to two hours of fateful agony. One of the best proofs that tubal peristalsis is premenstrual pain, is that that the pain is periodic, or worse at menstruation. When the automatic menstrual ganglia are at their climax of activity, the tubes are most active in motion. They are most congested, and adding new secretions to the already pathological one. These new secretions only intensify the irritations and increase the tubal peristalsis which simply adds agony to suffering. However, in these diseases the automatic menstrual ganglia work their own destruction. They are over-excited by irritative secretions, and in this over-excitement and super-peristalsis of the tubes the

muscular walls are rapidly dilated (by action and pressure of new-formed tissue), until the muscular layers are too thin or too much destroyed to respond to the ganglia, and thus the tubal colic loses some of its acuteness. The woman then becomes a real invalid, instead of a really acutely sick woman. It would be hopeful if the woman with diseased tubes could look for her deliverance from misery at the menopause, when the automatic menstrual ganglia will cease their temporary functional activity, but this she cannot always do, from the very fact that the disease has for years involved the contiguous tissue and organs. The disease has boldly progressed into fields foreign to the tubes, and left the woman with a damaged organism which no menopause can remove, and the head and front cause of tubal disease is gonorrhœa—a present spreading luxury of modern refined civilization.

MEDICAL PROGRESS.

CAPACITY OF THE SPINAL CANAL.—The results of certain experiments undertaken by Professor Reid and Dr. Sherrington, with a view to determining the result of position on the capacity of the spinal canal, are related in the last number of *Brain*. The plan of experiment was as follows: After trepanning over the vortex close to the longitudinal sinus, the dura mater was removed to an extent corresponding with the trepan hole. Water was then poured into the subdural space until it filled it, and a glass tube was next secured in the hole in a perfectly watertight fashion, a thin membrane which floated on the water filling the subdural space, having been previously drawn over the end of the tube.

A piece of glass tubing was connected with the other tube by flexible water-tight joints, the farther end of this tube being on a level with the trepan hole in the skull. Finally, this tube and its connections were filled with water and its free end projected over the scale pan of a sensitive balance, the other arm of which had a recording apparatus marking a revolving cylinder attached to it. The cadaver was suspended by means of an iron coronet, and variations in position were with the aid of a horizontal bar from the vertical stand on which the body was hung. The conclusions arrived at are that the capacity of the cranio-vertebral canal is at its maximum when the body is hanging freely and vertically, that there is diminution in this capacity when the weight of the trunk and limbs is taken off, and also when the vertebral column is bent backward or forward. In other words, it is found by this method of investigation that the alterations in the curvatures of the spinal canal by various movements do influence the capacity of the canal,

but not to any great extent. This variation is found to be greater in the child than in the adult. The authors conclude by remarking that this increase is so small that it becomes difficult to conceive how in the suspension treatment for cases of tubes there can, as has sometimes been claimed, be any actual stretching of the spinal cord.—*Lancet*.

A NEW METHOD OF DRESSING THE CHEST IN PNEUMONIA, PLEURISY, PLEURODYNIA, ETC.—Apply the dressing on a large scale, in the same way that we now dress abrasions, bruises, etc.

If there is to be any cupping or other preliminary operation, have that attended to; then all the ingredients wanting are pure collodion and absorbent cotton in smooth layers, and a good broad brush, like mucilage brushes.

Apply a very thin layer over the side affected from spinal column to sternum, and secure it with collodion smeared thoroughly over it. Then go on with thick layers, securing them with collodion until a good padding is obtained, paying particular attention to the edges. In double cases you can act accordingly. The advantages are:

1. The one dressing, if well applied, will last throughout the case, and so,
2. The fatigue and discomfort of frequent poulticing are avoided.
3. The side, in single cases, is held as in a splint, while the free side does the breathing. A first-class non-conductor is covering the chest. I am not sure but that the contracting collodion may have some influence in controlling the blood supply.
4. There is no particular interference, in one who has a good ear, with physical examination. May be it would be a good thing if there was; for, once having made the diagnosis, what is the use of exhausting the patient every day by trying to find out whether one-eighth of an inch, more or less, is involved? The general symptoms will tell that.—*Arch. of Gyn. and Pæd.*

INFECTION THROUGH THE SOIL.—The question is often raised whether there is any direct or indirect proof of the infectivity of the bodies of those dying from specific fevers, or whether the soil of graveyards may become really dangerously contaminated thereby, but it is also one to which comparatively little attention has been given by the experimentalist. One aspect of the matter has been lately studied by Dr. Justyn Karlinski, of Konjica, Herzegovina, in a series of experiments (*Centralblatt f. Bakteriologie*, ix, 13) undertaken to determine whether the organs of the body undergo any change in temperature during the natural process of decomposition after burial in the earth, and especially whether any differences in this regard are to be met with in the case of infected subjects. His results show

that invariably the putrefactive process is accompanied by a rise of temperature above that of the circumjacent soil; and also that this rise in temperature is markedly higher when the parts examined have been taken from the bodies of men or animals who have succumbed to infective diseases than it is in the case of healthy bodies. He further examined into the question of the survival of the pathogenic bacteria in the affected parts, and states that the typhoid bacilli may retain their vitality in the decomposing spleen for three months, and are only completely annihilated by rapid putrefaction and the presence of a large number of the bacteria of putrefaction. Dr. Karliński says that he had previously shown that typhoid bacilli could retain their vitality for a period of five months in soil, but that if the earth were thoroughly saturated with rain water they were destroyed in from seven to fourteen days. The part played by the soil in the origin of epidemics should not, he thinks, be under-estimated, since typhoid bacilli can only exist in water a comparatively short time.—*The Lancet*.

A MOTHER'S RESPONSIBILITY.—The child's doctor is daily impressed with the thought that there should be a special chair in every school for girls, for the purpose of accomplishing a mild degree of training in the direction of maternal duty. The innocent ignorance of mothers has much to do with occasioning disease in their children. Allusion is not made now to the neglect of hygiene, but to the failure on the part of the mother to recognize that she has in her child a bundle of nerves far more sensitive than her own. How often we see children that are fed and immediately afterward trotted and churned to the point of complete indigestion, and when discomfort results, they are given more of the same treatment. An incident noticed to-day in the round of practice, reminds me that even among those seemingly intelligent we find errors of this kind committed. The mother of the little one to whom we were called, backed up by her grandmother, insisted that when the baby, after nursing heartily, evidently had wind upon its stomach, that shaking and trotting upon the knee would assist in its relief. When asked how she would like it if, after being overfilled with food, some one eight or ten times as large should take her and pound her up and down with a view of adding to her comfort, she realized the point that was made. She is not the only mother, and grandmother as well, who though well informed in other directions, is ignorant of the fact that babies are but miniatures of ourselves: that their feeding should be systematic; that the proper material given and the quantity not too much but just enough, and that immediately following the meal, a restful position is preferable to excitement and exercise.

In the infant, regularity of feeding and restfulness after feeding should be insisted upon. We started out to draw attention to the failures of mothers to pay due respect to the nerves of their offspring, not only in infantile life but all during child-life. Abruptness, harshness, fretfulness and irritability upon the part of the mother will beget the similar conditions in the child, and how often have we seen the little one punished for following the example set by its mother.

What a pity that the strong-minded women of the world do not centre their intellectual efforts toward the education of the mothers of the land in the direction of the better care of their babies. Unfortunately, excessive intellectual development on the part of woman not only takes her away from the field of fruit-bearers herself, but also develops her taste for things foreign to her nature. The problems connected with social life and the home might be elucidated for the general good, if these great women thinkers and workers did their duty; but maternity, domesticity and wifehood seemingly are farthest from the consideration of these metal amazons. Suffrage, statecraft and teetotalism seem more to their tastes. They forget, apparently, that which tends much to the good of the world is expressed in the lines that

"Let man rule the world, 'tis nature's plan;
While woman, by her sweetness, governs man."
—*Medical Mirror*.

PATHOLOGY OF GRIEF.

That severe mental distress or fright sometimes produces physical disease, and occasionally even death, is an admitted fact, although the way in which it acts has hitherto been but little studied. In order in some measure to supply the deficiency in our knowledge regarding this matter, Dr. G. Bassi has recently made a number of observations on animals which apparently died in consequence of capture. Birds, moles, and a dog which had succumbed to conditions believed by Dr. Bassi to resemble those known amongst human beings as acute nostalgia and a "broken heart" were examined post-mortem. Generally there was hyperæmia, sometimes associated with capillary hæmorrhages of the abdominal organs, more especially of the liver, also fatty and granular degeneration of their elements, and sometimes bile was found in the stomach with or without a catarrhal condition. The clinical symptoms were at first those of excitement, especially in the birds, these being followed by depression and persistent anorexia. The theory suggested by Dr. Bassi is that the nervous disturbance interferes with the due nutrition of the tissues in such a way as to give rise to the formation of toxic substances—probably ptomaines—which then set up acute degeneration of the parenchymatous elements similar to that which occurs in consequence of the action of certain poisonous substances such as phosphorus, or to that met with in some infectious diseases. In support of this view, he points out that Schule has found parenchymatous degeneration in persons dead from acute delirium, and that Zenker found hæmorrhages in the pancreas in persons who had died suddenly; he refers also to some well-known facts concerning negroes in a state of slavery and to the occasional occurrence of jaundice after fright.—*The Lancet*.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,
CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

LONDON OFFICE, 57 AND 59 LUDGATE HILL.

SATURDAY, JULY 4, 1891.

BY-LAW IV OF THE AMERICAN MEDICAL ASSOCIATION.

The Publication of Papers and Reports.

No report or other paper shall be entitled to publication in the volume for the year in which it shall be presented to the Association, unless it be placed in the hands of the Board of Trustees on or before the first day of July. It must also be so prepared as to require no material alteration or addition at the hands of its author.

Authors of papers are required to return their proofs within two weeks after their reception; otherwise they will be passed over and omitted from the volume.

Every paper received by this Association and ordered to be published, and all plates or other means of illustration, shall be considered the exclusive property of the Association, and shall be published and sold for the exclusive benefit of the Association.

The Board of Trustees shall have full discretionary power to omit from the published *Transactions*, in part or in whole, any paper that may be referred to it by the Association, or either of the Sections, unless specially instructed to the contrary by vote of the Association.

NE TENTES AUT PERFICE.

It is apparent, to even the careless reader of the daily papers, that medical topics are receiving vastly more attention than ever before. It is even hinted that many large daily papers have a medical man on their regular staff; if such is the case they have generally succeeded in concealing the fact by displaying a phenomenal ignorance regarding medical subjects.

We clip the following from a prominent Chicago daily, whose medical department has lately occupied itself in exploiting Dr. Keeley's cure of inebriety, and the Shurly-Gibbes method of treating consumption as exemplified in the practice of a young Chicago physician:

A recent article in *The Tribune*, based on "Lagrange's Physiology of Bodily Exercise," explained the philosophy of the process by which great suffering or death follows undue exercise of the muscles in man, horses, and other animals. It is a fact amply demonstrated by the scientific physiologists that every exhibition of muscular force is accompanied by a disintegration of tissue, the quantity of matter thrown off being proportional to the amount of exertion. This material is carried by the veins to the lungs, where it combines with inspired (in-breathed) oxygen to form carbonic acid gas and is then expired into the atmosphere. If that effete matter be supplied to the lungs faster than it can be taken up by the oxygen, the uncombined portion acts as a poison. The effort of the system to get rid of it before succumbing to its deadly effects manifests itself in what is popularly known as "shortness of breath," though this is a misnomer, the difficulty experienced being not in filling the lungs but in getting rid of their contents. The greatest muscular exertion of which man or horse is capable furnishes this poisonous matter at least twice as fast as it can be thrown off immediately. If the action be brief the system soon finds relief, but if too long continued the poisonous accumulation becomes greater and greater till at last the animal succumbs and drops dead on the track—suffocated in the gas created by over-exertion. It is poisoned just as truly and as effectually as if it had taken a dose of the most deadly drug known to the chemist, or had breathed marsh gas or carburetted hydrogen gas.

While we must commend the article as a whole, leveled as it is, at a grave and unnecessary cruelty, we can but smile at the ponderous editorial cerebration that emitted the above physiological doctrines.

THE BACTERIA DESTROYING SUBSTANCE OF THE BLOOD.

In a preliminary communication M. OGATA, of the Hygienic Institute of Tokio (*Centralblatt für Bakteriologie und Parasitenkunde*, May, 1891), refers to some of his earlier researches upon the effect of the blood of certain species upon the bacillus of anthrax and mouse septicæmia. At that time he was unable to say what substance was contained in the blood of these animals which conferred the special power over these particular bacteria. For some time he has been experimenting with reference to this subject, and he is at last able to announce that he has discovered in dog's blood a substance that confers immunity.

This substance is obtained by a chemical process similar to that employed for precipitating complex proteids, and is called a "ferment" by the writer. We give his conclusions:

The substance is readily soluble in water and glycerine, but not in ether or alcohol, though the latter do not destroy its action. Its power is not affected by weak alkalis, but is by carbolic and hydrochloric acid. Its properties are destroyed by the digestive juices, and by heating to 45° C. The substance has decided "immunizing" as well as disinfecting properties, that are retained for a long time in a glycerine extract. It does not convert fibrin into peptone, nor starches into sugar.

EDITORIAL NOTES AND ITEMS.

A UNIQUE CASE.—We extract the following from the last issue of the *British Medical Journal*: "A nice point of law has lately been debated before a French court. The question was whether an operation on a dead body by an unqualified person came within the meaning of the enactment forbidding the illegal practice of medicine. It appears that a pregnant woman had just died, the cause of death not being stated. The curé of the village, who had been with her in her last moments, induced a neighbor who was in the room to perform Cæsarean section on the corpse with a view of saving the child. The operation was successful, but the operator was brought before the magistrate and fined 15 francs for having been guilty of illegal practice of medicine."

ANOTHER CASE OF HYPERPYREXIA.—In this *Journal* of date March 21st, 1891, appeared the report of a case of hyperpyrexia by Dr. Galbraith, of Omaha, Neb., and now we learn of another case equally quite as unaccountable, and which was reported at the May meeting of the Memphis Medical Society by Drs. Jones and Sale. The patient was a girl fourteen years of age, of bright and happy disposition, of good family, and "thoroughly trustworthy." There does not seem to be any chance or object for deception, the readings being taken in full sight and with the clothing removed. The mouth, axilla and rectum were the parts tested by numerous thermometers, and a considerable number of observations were made. No less than eight thermome-

ters were broken because not admitting of a sufficient expansion of the mercurial column. An instrument was ordered which would register as high as 150° F. Observations with this thermometer showed normal, then 115°, subsequently 135°, and still later 150°. After this it was placed in the axilla, when the expanding mercury destroyed the instrument. The rise in temperature is of but short duration. Altogether the case is striking, and does not at present admit of an easy solution.

THE ASSOCIATION OF GERMAN ALIENISTS will meet at Weimar on September 18 and 19. Among the questions to be discussed are the following: "Prophylaxis of Tuberculosis in Lunatic Asylums," "Responsibility and Criminality," "Drunkenness in Relation to Responsibility," "The Present Condition of the Aphasia Question," "Care of Epileptics," "Employment of Hypnosis in Lunatic Asylums."

JEWISH IMMUNITY TO CANCER DENIED.—B. W. Richardson (Asclepiad) denies the statement recently put forth of an almost, if not total, immunity of the Jewish race from cancerous affections. This observer has had no inconsiderable number of cancerous cases in Jews under his care, and found no noteworthy difference in the occurrence of the disease. Tuberculosis, however, he maintains is, according to his observations, much less prevalent in Jews than in Christians.

ENGLISH ESTEEM FOR AN AMERICAN PHYSICIAN.—Very outspoken expressions of esteem are observed in the English medical press regarding the late Dr. Fordyce Barker. Dr. Barker frequently visited upon the other side of the Atlantic, and always had an earnest welcome in the conferences of the first medical bodies in England. His worth was fully appreciated, and his nobleness and geniality recognized.

SENN'S METHOD OF INTESTINAL ANASTOMOSIS.—At the Surgical Clinic of Tuesday, June 23rd, at Rush Medical College, the spectators had the first opportunity during Prof. Senn's present incumbency of observing the operation for the production of an intestinal anastomosis between the lower part of the ileum and the transverse section of the colon, thus severing from the fecal circulation the ileo-cæcal portion of the gut. The operation was done for the relief of malignant disease involving the head of the colon,

Senn's method, by means of the longitudinal incision and the employment of the decalcified bone plates, was used. The operation, together with Parker's exploration of the post-cæcal region, and all of which was conducted by easy stages, required about one hour and twenty minutes, and was highly interesting throughout.

SOCIETY PROCEEDINGS.

Pennsylvania State Medical Society.

Forty-first Annual Session.

The society met at Reading, June 2d to 5th, there being over 300 delegates present from all parts of the state. The annual address by DR. ALEX. CRAIG, the president, was devoted to the consideration of the changes which have occurred since the organization of this body at the same place in 1849. At the present session, the incorporation having been accomplished, it now met as an incorporated body. The delegates in many instances came in stage coaches and numbered from nine counties. He alluded to the recent failure of the effort to obtain from the State Legislature a law to create a Board of Medical Examiners. All others are protected by law except the doctors.

Over 2,000 copies of the Transactions are distributed yearly, the cost being defrayed by an assessment upon each county society. A committee was appointed to aid the committee on the Rush monument of the American Medical Association, of one from each county.

The address in medicine by DR. J. C. LANGE, of Pittsburgh, was devoted to

THERAPEUSIS: NEW REMEDIES AND THEIR USE BY THE PROFESSION.

He alluded to the present method of forcing the many proprietary remedies upon the market, the obtaining of certificates and the ethical question connected therewith. The delusions of condurango, chian turpentine, kairine, the antipyretics, etc. The latest, called by an unscientific name, capitalized with thousands of dollars, is alleged to be fraudulent and to consist of an amelide and bicarb. of soda. Yet the medical journals are liberally supplied with commendations of it as an analgesic, antipyretic and anodyne. Indeed, a professor of therapeutics, during the last winter, dwelt upon it in his lectures in such a manner that students were in doubt, so wide was its usefulness, as to which deserved first rank, this or opium. Nothing succeeds like success, hence the advertiser invites us to call at his works and supplies us with knives, blotters, etc. He alluded to the value of the certificates printed, etc.

DR. A. B. BRUMBAUGH, of Huntingdon, delivered the

ADDRESS IN HYGIENE,

which forcibly depicted the errors so constantly found in homes, etc., in the sanitary surroundings, leading to diphtheria, typhoid, etc.

A paper by DR. BATTEN, Pittsburgh, on

TAPE WORM,

was devoted to that form originating from the use of raw or poorly-cooked beef, this being the form most frequently encountered. His treatment was the use of the oil of turpentine, tablespoonful doses, after a light meal. In one case he ordered fasting for a week and the use of vinegar in quantities as much as could be drank. Another took the pumpkin seeds with turpentine, fasting. In each the worm was expelled and a cure followed. He then alluded to the use of kameela, and male fern, chloroform, cocoanut, etc., regarding these equally good, sometimes requiring a variation, according to results. A spirited discussion followed, showing the tænicides to be much less limited than had been believed.

A very interesting paper by DR. CLEAVER was entitled

THE HISTORY OF THE MEDICAL PROFESSION IN BERKS COUNTY.

The report of the Legislative Committee gave some idea of the intricate mazes to be threaded by those who endeavor to obtain legislation for the benefit of the profession, the bill having passed after numerous amendments in the upper house, only to be killed by the efforts of the irregulars and others who pretended to oppose "class legislation." In spite of this the society determined to persevere, and the committee was continued this year, the legislature not meeting till 1893, to work up the profession throughout the state, so that in the next effort the support would be more earnest and beneficial.

DR. J. M. ANDREWS read a paper on

SUBACUTE PLEURITIS.

He believed that a single full dose of antifebrin would abort some cases. In a cachectic case, digitalis is useful. Quinine is of great value. Effusion occurring, what is to be done? We must limit or arrest the effusion, and when present, remove it. Combat the inflammation, rub in iodine freely on the chest, eschew blisters, poultices, and the like, as they increase the amount of fluid. Absorption may occur unless the proportion of leucocytes is great. Arterial sedatives are injurious. So with antipyretics after the effusion. Quinine is of great value; 2 grains every three hours, till the temperature falls. The removal of the effusions important. Diaphoretics are objectionable, they depress too much, especially jaborandi. Iodide of iron is

the best remedy to promise absorption, 10 drops with 5 grains of iodide of potash every four hours. Under this in twenty cases, aspiration was needed only in four. How long shall we wait? Don't delay more than one week. That is from the time the temperature has reached normal. In paracentesis draw off half a pint, repeat every second day till absorption has rightly commenced. This allows the compressed lung to expand gradually. It obviates the dangers of congestion, œdema, albuminoid, expectoration, cyanosis, etc. During convalescence, assist the expansion of the lung, improve general health. Change of air, tonics, as from oxygen and good diet. Deep inspirations to aid the complete restoration of the lung, exercise and light gymnastics follow, and if needed strychnia, electricity, etc.

DR. W. F. WAUGH, of Philadelphia, read a paper on the

TREATMENT OF TYPHOID FEVER WITH THE
SULPHO-CARBOLATE OF ZINC,

claiming most excellent results from the history of many cases.

DR. HIRAM CORSON, of Norristown, Pres. of this society in 1852, had a resolution passed urging the appointment of a woman on the Board of Public Charities. A committee was appointed to urge this upon the Governor of the State.

Wednesday afternoon was devoted to consumption. DR. T. J. MAYS, of Philadelphia, read a paper the *Contagion, Theory and Treatment*, and DR. HUGH HAMILTON, of Harrisburg, on the *Physiological Behavior of Koch's Remedy*. Papers in discussion were read by Drs. C. W. Dulles, of Philadelphia, W. T. Bishop, of Harrisburg, L. H. Taylor, of Wilkesbarre, and others. The argument seemed rather opposed to the benefit of Koch's lymph and the contagion theory.

DR. FLICK, of Philadelphia, insisted strongly that certain houses became centres of this disease, and quoted his former paper on the 5th ward of Philadelphia, which he had so thoroughly investigated. Much interest was shown by the entire body in this discussion.

DR. O. H. ALLIS, of Philadelphia, read the

ADDRESS ON SURGERY,

giving problems in surgery in a conversational way. He spoke of the impropriety of Choparts, Pirogoffs, of similar operations as rendering the leg nothing but a peg leg, not useful for running, or the employment of an artificial leg, in short he insisted that in all such cases amputation should be below the knee so that a leg might be applied on which the patient could walk, run, in short being equal to the real leg. He suggested the idea of endeavoring to unite the ends of divided arteries, perhaps the insertion of a joint when the joint anywhere was destroyed, the cutting out of a portion of bone to permit the sutur-

ing of nerves, where otherwise the union could not be obtained, the resection of the fibula when false joint of the tibia occurred, illustrating his address by excellent diagrams and calling down the house, when he had concluded, by his masterly and convincing way of talking. The surgeons present attacked some of his views, but all admired them.

DR. PRICE, of Philadelphia, illustrated his coincidence as to the amputation below the knee by quoting and exhibiting his own case; he had an amputation just below the knee, and rode, mounting from either side, walked many miles on gunning trips, and emphatically declared that he would prosecute any one who would amputate his leg so as to leave a stump not suitable for an artificial leg. One objected that Chopart or Pirogoff operation was better for a poor man not able to buy an artificial leg and yet could shovel earth, etc., with a stump left as long as possible. Several railroad surgeons participated in this animated discussion and quoted their results in that kind of work.

DR. E. E. MONTGOMERY, of Philadelphia, read a paper on the

CONDITIONS FOLLOWING PARTURITION REQUIRING ABDOMINAL SECTION.

Formerly patients were permitted to die with large collections of pus in the abdomen. These could have been washed out and life saved. Now we know the value of vaginal and intra-uterine antiseptic washing. The curette has become of great importance to remove decomposing material, and then irrigate to render the cavity sterile. Mortality is thus greatly reduced, but when the disease has extended beyond the uterine mucous surface, peritonitis, metritis, salpingitis or ovaritis follow. Here abdominal section is imperative. We find often small ovarian tumors, these may be bruised or ruptured in parturition. Section enables their removal, irrigation, asepsis and safety.

Tubal disease, pus collections in the tubes, are reported, large fibroids; each aids to develop sepsis and death. Retention of the placenta, in part or clits, will produce sepsis. He related many cases to prove how readily the operation could be done, and its sure value.

In abscess of the uterine walls, he prefers extirpation of the uterus. He did not urge the section in every case of sepsis; he would first determine with great care the avenue of the poison to enter the system—as in a case, where there was abdominal sensitiveness, after a very difficult labor, temperature 103°, ether was given, and search revealed a laceration through the peritoneum into the rectal septum. A profuse, extensive lochia was discharged. The tear extended to the ischial tuberosities, and on the left into the broad ligament. No incision here was deemed

necessary, the sutures were removed, thorough irrigation performed, and the wound treated as an open one. Temperature subsided, but the next day rose to 106°, when she was placed on a blanket, wrapped in a sheet wrung out of ice-water, bathed in ice-water, given 10 grs. of acetanilide hourly for three doses, followed by rapid convalescence.

In sepsis he urged careful examination as to the avenue, and its elimination.

If no vaginal or vulvar laceration, dilatation of the uterine, curetting the cavity, and irrigation.

Accumulation in the pelvis, etc., the prompt opening of the cavity, removal of diseased organs, irrigation and drainage.

Where no cause is found in the pelvis, curetting, etc., have no influence. An exploratory incision will determine whether small pus collections in the organs serve as centres of poison. Even puncture the ovaries, as it, with the antiseptic knife, will not harm. Remove the uterus where its walls are abscessed. Remove promptly fibroids in the uterine walls. If there has been reason to suspect the presence of small dermoid or other ovarian cysts, and their injury in parturition, section is indicated urgently.

Drs. J. M. Duff, Pittsburg; M. Price, Philadelphia; John C. DaCosta, Philadelphia, and others, differed greatly, some counseling prompt action, others showing a conservative spirit, and detailing cases where good results followed, even in apparently desperate conditions, though section had not been practiced.

The next paper was by DR. EDW. JACKSON, Philadelphia,

WHAT TO DO IN INCIPIENT CATARACT,

taking the ground of operating when the opacity had become such that vision was obscured, and showing instances where delay had not proved objectionable, as well as the regular treatment which he had found of benefit in the early stages.

DR. J. A. LIPPINCOTT, Pittsburg, read the Address in Ophthalmology, dwelling on contagious ophthalmia as so often seen in orphan homes, etc., and the danger of the indiscriminate use of towels, etc. A Committee on Contagious Ophthalmia was afterwards appointed, with Dr. Lippincott as chairman.

Some time was devoted to the amendment of the By-laws, as in the articles of incorporation certain points had not been considered, and after this session it required all changes to lie over for one year.

The Address on Obstetrics was by DR. J. M. DUFF, Pittsburg, who reviewed the year's work in this department.

Asepsis, although so important, was still ridiculed by some, or performed in a careless way, with bad results. A 2 per cent. solution of creoline seems to have preference, in intra-uterine

uses, or a 3 per cent. of lysol, while many land the use of benzine as a safe and powerful germicide. The sulphate of copper in 1 per cent. solution is quoted as not being followed by a single case of septicæmia. No poisoning or bad results were seen. Roberts thinks it aids involution. Peroxide of hydrogen in a few cases has led to its being highly prized. The immediate repair of lacerations is aseptic, and prevents later troubles.

The imperforate dressing of Garrigues is indispensable.

Menstruating nurses are not necessarily dangerous, unless wanting in cleanliness. A putrifying funis may infect both mother and child.

Puerperal fever, owing to asepsis, is much decreased.

Septicæmia is now puerperal infection. Sapræmia affections are amenable to treatment, are caused by the alkaloids of putrefaction from retained placenta and clots. Septicæmia diseases are virulent, produced by direct absorption, probably from ptomaines. Curetting the womb is urged and devoid of danger. In suppurative peritonitis, abdominal incision and immediate washing out and drainage. In severe flatulence, the trocar is recommended.

Eclampsia: Albuminuria is a causative—eliminate and give chloroform, 10 to 20 drops in water before meals. Urine will increase and albumen diminish. The wet pack is a prophylactic. Veratrum, hypodermically, acts well.

Placenta prævia is diagnosed by palpation. Untoward symptoms require prompt delivery by Braxton Hicks' method.

Post-partum hæmorrhage is treated by tampon of iodoform gauze, and hydrastin and hypodermic injections of caffein in benzoate of soda. Kochs inverts the uterus, puts an india-rubber band around the neck of inverted part, a few hours after removes the band, reduces the inversion, gives ergot and kneads.

Rupture of uterus requires laparotomy.

Ectopic pregnancy is more frequent, once in 500 pregnancies. Electricity, removal as soon as known, are each advocated by good authority.

In abortion nothing new is said.

Electrolysis, cellulitis, contracted pelvis, were each treated.

Fluid extract of galactaga was highly vaunted as a galactagogue, and antipyrin as in opposition.

Mammary abscess is not always to follow cracked nipples.

The whole paper teemed with matters of interest, and was enriched with a full bibliography.

DR. S. SOLIS-COHEN addressed the Society on "Patent Medicines and the Newspapers."

DR. C. R. EARLEY, Ridgway, spoke on "Catarrh," and gave an interesting account of the medication, etc., of the olden time.

DR. J. AULDE, Philadelphia, spoke on the "Therapeutics of Euphorbia Pilulifera."

The Society closed this, one of its most interesting and successful sessions, on Friday, by the selection of the following officers: President—Dr. S. L. Kurtz, Reading; Vice-Presidents—Dr. J. B. Roberts, Philadelphia; Dr. H. G. McCormick, Williamsport; Dr. H. H. Whitcomb, Norristown; and Dr. I. C. Gable, York; Secretary—Dr. Wm. B. Atkinson, Philadelphia; Assistant, Dr. C. W. Dulles, Philadelphia; Treasurer—Dr. G. B. Dunmire, Philadelphia, and Censors for the thirteen districts and delegates to the American Medical Association, etc. Next place of meeting, Harrisburg, third Tuesday in May, 1892.

The Address in Medicine for 1892, Dr. J. H. Musser, Philadelphia; in Surgery, Dr. T. D. Davis, Pittsburg; in Obstetrics, Dr. H. G. McCormick, Williamsport; in Mental Disorders, Dr. J. W. Phillips, Clifton; in Hygiene, Dr. A. A. Woods, Erie; in Otology, Dr. G. R. Rohrer, Lancaster.

Drs. C. G. Loose, W. T. Bishop and T. M. Livingston were appointed a delegation to the State Pharmaceutical Association.

Philadelphia County Medical Society.

Stated Meeting May 29, 1891.

THE PRESIDENT, JOHN B. ROBERTS, M.D., IN
THE CHAIR.

DR. FRANK WOODBURY submitted a paper on
NITROGEN-CONTAINING FOODS AND THEIR RE-
LATIONS TO MORBID STATES.

In connection with the paper of the evening, by Professor Chittenden, upon the "Food-value of Beef-preparations," I have been invited by the Honorable Board of Directors to contribute a few remarks upon "Nitrogen-Containing Foods and their Relations to Certain Morbid States." Under the circumstances, it is proper that what I have to say shall be made as brief as possible.

At the outset, our attention is drawn to some fundamental physiological facts which must be kept in mind during the discussion of this subject. The human body is now regarded as a unit composed of an aggregation or community of cells. These anatomical elements differ from each other in some respects, but agree in this: each cell consists of two parts, one living and one non-living, corresponding with cell-nucleus and formed material. What is visible to us is the non-living part, or the formed material; the real living part of the organism is hidden from view. Just as in vegetable tissue, the parts that are permanent and solid are composed of the cell-walls, which may remain long after the essential living part or protoplasm of the wood-cell has dried up and disappeared—in a similar way, in

the human subject, the various organs and tissues which give it form and substance are not living; the only part exhibiting vital phenomena is the soft, shapeless, and colorless cell-nucleus, consisting of protoplasm or bioplasm. This living substance, in its chemical composition, resembles the various tissues, varying somewhat according to function, but it contains one essential ingredient which is so characteristic as to confer its name upon the whole class—this element is nitrogen. The celebrated dictum, "Without phosphorus, no thought," might be paraphrased "Without nitrogen, no life." Viewed from the physiological standpoint, the name "Azote," applied to this element by Lavoisier, appears remarkably inappropriate.

As a necessary constituent of the tissues, therefore, nitrogen, in a state of combination, is always present in the human body. Since it is found in considerable quantity and in various forms in the excretions, some two or three hundred grains being discharged daily by the kidneys alone, besides what is lost by the intestinal tract and the skin, it is evident that in order to maintain life the supply must be kept up from outside sources. There are two principal directions in which we may look for the supply of nitrogen, 1, the atmospheric air, and 2, the food.

Although the atmospheric air contains about 80 per cent. of nitrogen, we may dismiss this at once as not available, beyond a very limited extent. Experiment has shown that it is not consumed or absorbed in the act of respiration; but a certain amount of air is always swallowed with the food and passes into the stomach, where it may become absorbed by the gastro-intestinal mucous membrane. It is possible that a small quantity is introduced by this channel, especially since it has been demonstrated that a moderate amount of gaseous nitrogen is excreted or exhaled by the skin.

Nitrogen-containing food must, therefore, be regarded as practically the only source of the constant supply of nitrogen which is so essential to the maintenance of the body in a normal condition. In fact, due attention has already been given to this by Liebig, Fick, Wislicenus, Parkes, Pavy, Flint, and others; and the proper relation of the two great divisions of proximate principles of organic origin, the nitrogenized and the non-nitrogenized, have been pretty closely determined. As their results are to be found in all the text-books, I will not refer to them in detail. I may remark, however, in passing, that from the clinical standpoint there appears to be a fallacy underlying all these calculations of dietaries, where food values are expressed in grains of nitrogen and carbon, inasmuch as no allowance is made for waste; the entire quantity ingested is supposed to be digested and assimilated. In

practice we know that the feces contain considerable nitrogen, which is not excretory, properly speaking, but represents the excess of consumption, part of the food having escaped digestion. In nursing infants the feces consist largely of undigested casein. Even adults are not able to entirely digest milk, and if so simple an article of food as milk is not completely assimilated, what warrant have we for assuming that the nitrogenized constituents of peas and beans, or of animal tissue, will yield their full equivalent of potential force to the organism? On the contrary, we know it to be a fact, that much food-stuff passes through the alimentary canal without having its proximate principles extracted by the digestive organs and the absorbents.

We may, however, both clinically and by physiological experiment, making due allowance for personal equation, determine with sufficient exactness the kinds and proportion of different foods required to maintain the body in a normal condition. Proceeding on the same lines, we may discover the effects of an excess, actual or relative, of nitrogen; or, on the other hand, we may ascertain the results of deprivation, either partial or complete. We may also be able to see some therapeutic applications of the knowledge thus gained.

From the time of Hippocrates, and even earlier, it has been known that health and disease are largely influenced by food, and the effects of an animal diet are different from those of a diet exclusively of vegetables. A distinction was even made between leguminous and other forms of vegetable food. It was not until our day, however that the practicing physician possessed sufficient knowledge of the chemistry of food and of metabolism in health and disease to enable him to direct the diet of his patients upon scientific principles. Following the definition given by Hippocrates: "Medicine consists in addition and subtraction, the addition of the things which are deficient and the subtraction of those things which are redundant; he who practices this is the best physician, but he whose practice is farthest from it is the farthest removed from a knowledge of the art"—we can now prescribe viands suited to a deficiency of nitrogen in the system, or substitute others if there is an excess. To the therapeutic aspect of the subject I will now very briefly ask your attention.

Taking up the latter instance first, we find that a diet poor in nitrogen is useful in several forms of rheumatism, in gout and in lithæmia, and also in recurring attacks of biliousness and bilious headache. Scurvy appears to be caused by an absolute, as well as a relative, excess of nitrogen in the food, and I have seen it caused by the use of an excessive amount of fresh meat among children in an orphan asylum. In its treatment, vegetable food relatively poor in nitrogen is usu-

ally employed. Some skin diseases, possibly of lithæmic character, are only to be cured by withholding nitrogenized food. It seems possible that a liberal use of meat in the diet may have some connection with the development of cancer, a disease which appears to be on the increase, as was pointed out by Dr. R. A. Cleemann, of this Society, in his "Address on Hygiene," delivered before the Medical Society of the State of Pennsylvania a few years ago. Dr. W. Mattieu Williams, in a little work on the "Chemistry of Cookery," pointedly directs attention to the large consumption of meat as a cause of various forms of cancer. In families where a hereditary tendency of this kind exists, it is possible that it might be overcome by vegetarianism. Some nervous affections, notably epilepsy and chorea, are greatly benefited by abstention from meat in the food.

Owing to the writings of Roberts, Fothergill, and others, a causative connection between a diet rich in nitrogen and some forms of kidney inflammation or degeneration is now generally recognized. And in the treatment of the various forms of Bright's disease, attention to the diet is generally admitted to be of prime importance. There is a widely-spread opinion that nitrogenized food is favorable to the occurrence of inflammation, and for this there seems to be a scientific foundation. Parkes has shown that a non-nitrogenized diet causes lowered blood-pressure and diminished arterial tension. Meat, therefore, is ordinarily prohibited under the antiphlogistic treatment, as it was formerly called. In acute inflammations of mucous surfaces, especially in plethoric subjects, the use of animal food is usually forbidden. This should not be applied too strictly, however, for in some cases of sub-acute or chronic character, a generous and nourishing diet is necessary.

On the other hand, nitrogenized food may be prescribed where there is, from any cause, a deficiency of albuminous principles in the blood, for example, in anæmia or chlorosis. In phthisis, this condition is sometimes quite marked and good results have been obtained from the "beef and hot-water" plan of treatment, and also from the use of fresh bullock's blood, or hæmoglobin, which requires less digestive capacity and is more easily assimilated than muscle-tissue.

Children frequently suffer from a deficiency of nitrogen. Where an infant is reared upon condensed milk entirely, the limbs are plump but the tissues are flabby, on account of anæmia. Such children are late in getting their teeth, and have little power of resistance against disease. The addition of oat-meal, barley or rice to the milk will often bring about marked improvement and may prevent the development of rickets. Just here I might stop to point out the fallacious character of some of the arguments based upon the

comparative chemical composition of woman's milk and other foods. Leeds found in a number of specimens of woman's milk that the nitrogenous constituents varied from 4.86 to 0.85 per cent. So that one specimen of mother's milk may have six times the amount of albuminous material contained in another.¹ This shows the necessity when the child does not thrive at the breast, of examining the milk to find out if it be deficient in nitrogenized constituents. If so, the addition of beef, meal, bovine or other nitrogen-containing food in an easily-assimilable form is advisable.

Eczema in infants, or in sewing women, is often traceable to a deficiency of nitrogen in the food, and Dr. Rohé, of Baltimore, advises the addition of meat-broth and eggs to the diet as an essential part of the treatment. Similarly, in many syphilitic eruptions upon the skin, in broken-down subjects, good food is a necessary preliminary to any specific treatment. Neurasthenia and atonic dyspepsia, which are so often associated in the same patient, especially if he is at the same time anæmic, can only be relieved by nitrogenized and fatty food, administered in a form easy of assimilation and at comparatively short intervals. On the other hand, in diabetes and in obesity, the diet may be largely nitrogenous, but in this case it is because there is a desire to reduce the carbo-hydrates and not because an excess of nitrogen is particularly sought after.

To return to the children, I wish to call attention to the fact that during the period of growth and development, more nitrogen is needed than after the body has assumed its full stature. Hence, school-children should have a due allowance of meat, and should be encouraged to eat oat-meal, corn, beans, peas and other vegetables known to contain this valuable constituent.

In the foregoing brief *résumé* of an important and interesting subject, I have not made any distinction between the nitrogenous, proximate principles of animal and vegetable origin. Chemically and physiologically they are nearly identical; but practically there are minor differences of palatability, digestibility, and relative utility, which, at present, our limits will not permit us to consider.

SCIATICA.—At the clinic of Prof. Landou Carter Gray, of New York (*Practice*, Feb., 1891), much benefit has been obtained in sciatica from phenacetin, given in tablets of four to eight grs. every three or four hours. There are a good many cases, however, which do not respond to it very markedly. Doubtless, too, there are many cases of sciatic neuritis, rheumatism, gout, etc., in which a diagnosis of sciatica is erroneously made; but perhaps more frequently sciatica is mistaken for one of these affections.

¹ Quoted by Starr in his "Hygiene of the Nursery," Philadelphia, 1888.

FOREIGN CORRESPONDENCE.

LETTER FROM LONDON.

(FROM OUR OWN CORRESPONDENT.)

The London Student and his Degree—Defeat of the Senate of the University—Sir Walter Foster on Political Powerlessness of the Profession—Severe Hail and Influenza—Professor Gairdner's Little Story.

The London student is at length to have a degree on "reasonable terms," the present standard being—as every one knows—especially in preliminary scientific subjects, absurdly high. London enjoys the unique position of being the only metropolis in the whole civilized world that does not possess a teaching University. The Royal Commission of 1888, reported that the case for such a body had been made out. In fact, the want has been admitted on all hands, and a practical illustration of the evils of the present policy is ever-present in the steady exodus of London students to the provincial Universities. At length the Senate of the University, with the aid of the authorities of the Royal Colleges of the Physicians and the Surgeons so far threw off their slough of slumbering conservatism as to draw up a scheme for reconstitution. Defeat, however, has awaited their proposals on all hands. The provincial schools, which were practically ignored, at once raised the standard of revolt. The Council of the College of Surgeons had not consulted their members and fellows, who accordingly passed most adverse criticisms both upon the scheme and upon their Council on the first opportunity that offered itself. Lawson Tait, also, carried a resolution to the effect that the Society of Apothecaries ought not be excluded. The final blow was given at a meeting of the Convocation of the University, which threw out the proposals by an overwhelming majority. Nothing but a complete teaching scheme will satisfy the public and the profession. Some of the journals say in so many words that it is nothing but the instinct of self-preservation that has forced the London Senate to unbend so far as it has done. The spirit of reform, however, is abroad, and has invaded the precincts of these autocratic boards that have hitherto consulted no interests but their own, and have done their best to make close corporations of what should be national institutions.

One of the first men to call attention to the existence of such a thing as a democracy in the medical profession was Sir Walter Foster. In 1883 he made a famous speech as President of the Birmingham Branch of the Midland British Medical Association. In that address he pointed out the political powerlessness of the profession as a body, and thus started the wave of opinion that is now dashing against the outworks of various time-honored anachronisms. After twenty-three years service Sir Walter has just resigned his post as honorary physician to the Birmingham General Infirmary. Five years since he was elected direct representative on the General Medical Council, one of the greatest honors that could be conferred on a medical man in this country, and he is also a member of Parliament. On the occasion of his first entering public life he mentions that Sir Andrew

Clark wrote him a word of warning to the effect that "Medicine is a jealous mistress," to which he replied that the best antidote to jealousy was unbroken loyalty. Sir Walter added that in all his public life he never had, and he hoped he never should, lose sight of medicine, for he believed their profession was interwoven with the highest and best legislation and the future welfare of mankind. The latter appears to be very much the conclusion arrived at by most philosophical latter day thinkers, and may be otherwise expressed by saying that medicine is the most progressive, as it is the most comprehensive among the professions. After waiting all these centuries the outside world seems to be waking up to pretty much the same opinion. In England, it may be noted, public enthusiasm has not reached the length of making peers of the doctors; that honor, so far, is reserved for such people as soldiers, diplomats, bankers, brewers, and successful politicians. The claims of literature have long been conceded to be represented in the hereditary House. Medicine, however, has had only one representative, somewhere in the middle ages.

The severe winter is being followed by a late spring. Hail storms have been reported all over the country, varied with snow and sleet, and now and then a warm genial day is dovetailed into the midst of this backward season. The cold has had the effect of swelling the Registrar General's returns to a remarkable degree. In London alone there is an increase of 433 deaths above the average for the corresponding week in the last ten years. The deaths from diseases of the respiratory organs were 584, or 240 in excess of the average; of these 230 were attributed to pneumonia, 302 to bronchitis. Influenza reached the high figure of 148, or 21 in excess of the highest weekly number of deaths in the outbreak of 1890. The death rate of the Metropolis for last week has been 24 per 1000. In some of the provincial towns, moreover, the rate has been more than doubled. During the last three weeks, for instance, the following returns have been made from provincial towns; Sheffield, 57.8, 70.5, 59.3; Leeds, 27.9, 36.1, 48.3; Manchester, 29.8, 55.1, 43.6. A more intimate acquaintance with this mysterious disease brings the lesson that mortality is largely influenced by surrounding insanitary conditions. At the best of times Sheffield, which has suffered more than any other town in the present epidemic, is especially liable to affections of the respiratory organs. This is no doubt due to a great extent to its smoke-laden atmosphere and to the dusty workshops with which its staple hardware industries are necessarily associated.

The other day in Dublin, Prof. Gairdner revived a story that went the round in Edinburgh many years ago, and of which it may be said *Se non e vere, e ben trovato*. He asks whether it is better to test a harmless remedy by giving it all round, or to adopt the more scientific plan of giving it to one-half of our patients (reserving the other half as a control experiment). The story refers to the former method. "A lady, finding in her prescription something unwonted and, as she thought, uncanny, turned back to get a further explanation from the Professor, who by that time was fully occupied with some one else. But the man at the door was equal to the oc-

casion. Taking the prescription into his hand he ran over it with a practiced eye, inured even to Latin formulæ by long and faithful service in a medical man's house. He returned the paper to the lady and showed her to the door with the remark "Ou aye, mem, its a'richt, they're a' gettin' that, the now." The Professor had been experimenting all round, more or less, with some of the more unwonted salts, such as titanium, cadmium, tellurium, palladium and so on, most of which turned out to be tonics, with the exception of one, which had the awkward peculiarity of causing the patient to shed abroad such a peculiar and disagreeable perfume or stink (if you will pardon the word) that it had to be forthwith abandoned." As Dr. Gairdner remarks, the anecdote did not detract from the world-wide fame of the Professor in question, nor was it known to have emptied his crowded waiting rooms to any great extent. D. W.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

With the June meeting the New York County Medical Association concluded its labors for the present season. After the scientific exercises, the members adjourned to the supper-room below, where they made merry on strawberries and ice-cream, served in place of the ordinary collation, and were entertained with short congratulatory speeches by the President, Dr. McLeod, and others. Among the speakers were Dr. Truax and ex-Presidents Harrison and Shady, and the latter, in his genial way, related a number of reminiscences of medical life in New York in former days. The Association still continues in a very gratifying condition of prosperity, and, notwithstanding the fact that an unusually large number of its members have been removed by death during the past year, it adjourns for the summer with 648 names on its roll, as against 531 at the same time last year.

At this June meeting the first paper of the evening was by Dr. Edward Sanders, on "Chronic Induration following Pelvic Cellulitis in the Female, and its Treatment by Galvanism." His observations were based on no less than 200 cases personally treated by himself, and without going into the somewhat vexed question as to the part played by peritonitis in the production of the condition referred to, he made a careful analysis of the cases and presented a most valuable aggregation of facts as the result of his practical experience. In the vast majority of his cases, the pelvic induration found to be present was the result of parturition at term, or of abortion, and, after having tried various other methods of treatment, he had found that galvanism was by far the most efficient and satisfactory in every way. In fact, he said, he had yet to meet the first uncomplicated case of the kind, without any concomitant disease of the ovaries or tubes, that could not be entirely cured by this agent.

The more recent cases required but a comparatively short time for cure, but in those of long standing, it was necessary to keep up the treatment for a considerable

period. While the pain and other symptomatic features were often relieved after a few applications, the lesions did not disappear, as a rule, until the method had been employed for some months. Dr. Sanders is very particular as to the exact dosage and regulation of the galvanic current, always making use of the milliamperè-meter and the rheostat. He never resorts to puncture, believing this practice to be dangerous, as well as unnecessary. For the comfort of the patient he regards it desirable to have an electrode of large surface for application on the abdomen, and he usually employs a modified Apostoli electrode for this purpose. For the intra-vaginal electrode he uses a metallic ball, and sometimes one of clay. It is seldom or never necessary to use an intra-uterine electrode, as this is not only less efficient, but also much more painful, as a rule, than the intra-vaginal electrode. In general, he thinks a current of from 100 to 125 milliampères, maintained for about five minutes at a sitting, and repeated about twice a week, is that which will be found most satisfactory; though in exceptional instances he has employed a current of the strength of 200 milliampères. The battery, a Wait and Bartlett, which he habitually uses in his office, has sixty cells; but he stated that one of forty cells would answer every purpose.

The second paper of the evening was by Dr. T. H. Manley, who took for his subject "Resection as a Substitute for Primary Amputation." In it he made the somewhat startling claim that, in civil life, a primary amputation is never a justifiable amputation; and it was devoted to a strong and carefully prepared plea for conservatism in surgery. The plan of treatment which he advised, he said, was based on modern experience and teaching, and it included, in the first place, efficient asepsis or antisepsis; and, in the second place, proper conservation of the tissues. It should be the surgeon's endeavor to preserve all that had not been actually destroyed, and the method involved a thorough knowledge of modern osteoplasty. If seen early, the parts could be kept in an aseptic condition; but if septic phenomena had already made their appearance, suitable antiseptic measures were called for. Bichloride of mercury was undoubtedly the most efficient antiseptic agent at our command, but care should be taken not to use it in too great strength; a solution of the strength of 1 to from 5,000 to 10,000 being the most satisfactory.

Antisepsis, he believed, had been used too much by surgeons. When a strong bichloride solution was employed, he had frequently found that a useless stump was the result, on account of the extreme sensitiveness of the parts. Moreover, he had frequently seen insidious osteomyelitis develop in the case of perfectly healthy subjects, where there was nothing to account for this untoward result but the use of powerful antiseptics. Hence, he said, he employed no antisepsis whatever if a septic process had already commenced; making use of nothing but sterilized water.

Resection, Dr. Manley contended, must not be confounded with restitution of structure, although very much could be accomplished by osteoplasty. In the shafts of bones, the great obstacle to success in treatment was medullary intolerance, and hence the fastening to-

gether of fragments by pegs and wiring was apt to be followed by osteomyelitis. The great reliance here, therefore, was to be placed on periosteal osteoplasty. In his concluding remarks he said that in his paper he claimed nothing new in principle; all that he claimed was a new application of principles already well established. In primary amputations it was well known that a second operation, involving the amputation of the limb at a higher point, was often called for. By delay, however, we did not put our patient's life in any additional danger; and if we succeeded in saving the limb, there was certainly a great gain, since a natural limb, even though it were only fairly useful, was unquestionably much better than any kind of an artificial one. Finally, there was the medico-legal aspect of the question to be taken into consideration. It was now generally understood by the laity, as well as the profession, that limbs could often be saved by the resources of modern surgery, which formerly would have been sacrificed, and therefore, any surgeon performing an amputation was liable to be summoned to answer to the charge of having removed a limb unnecessarily.

There were present as guests Dr. Wm. C. Wile, of Danbury, Conn., Editor of the *New England Medical Monthly*, and Dr. Quimby, of Jersey City, and both these surgeons spoke in warm approbation of Dr. Manley's conservative views.

Before adjourning the Association by a unanimous vote determined to send to the Judicial Council of the American Medical Association a memorial, prepared by a committee of which Dr. Robert Hinman was chairman, in reference to the eligibility as officers and delegates of the National Association, of physicians from the State of New York who are not in accord with the Code of Ethics of the Association.

This year the Commencement of the College of Physicians and Surgeons was held in connection with that of Columbia College, with which it has recently been consolidated as the Medical Department of the institution. There were 130 graduates in medicine, and in the course of his address the President, Mr. Low, spoke of the significance which this happily consummated union had for the cause of medical education in this country.

P. B. P.

ASSOCIATION NEWS.

Committees on Railroad Surgeons and Incorporation.

At the late meeting in Washington the President announced as the committee:

On Railroad Surgeons.—Ala., J. Cochran, Mobile; Ark., L. P. Gibson, Little Rock; Cal., G. G. Tyrrell, Sacramento; Col., John Elsner, Denver; Conn., T. D. Crothers, Hartford; D.C., J. Ford Thompson, Washington; Del., R. G. Ellegood, Concord; Fla., J. D. Fernandez, Jacksonville; Ga., T. S. Powell, Atlanta; Ill., B. M. Griffin, Springfield; Ind., J. F. Hibberd, Richmond; Iowa, G. F. Jenkins, Keokuk; Kans., W. L. Schenck, Osage City; Ky., J. M. McCormack, Bowling Green; La., T. G. Richardson, New Orleans; Maine, A. Garce-

lon, Lewiston; Maryland, G. Lane Taneyhill, Baltimore; Mass., A. L. Norris, Cambridge; Mich., J. E. Emerson, Detroit; Minn., Perry H. Millard, St. Paul; Miss., B. A. Duncan, West Point; Mo., G. W. Broome, St. Louis; N. C., Thos. F. Wood, Wilmington; N. H., G. P. Conn, Concord; N. J., D. Benjamin, Camden; N. Y., E. D. Ferguson, Troy; N. Dak., G. McLutye, Hillsboro; Ohio, S. S. Thorn, Toledo; Oregon, C. C. Strong, Portland; Pa., John B. Roberts, Philadelphia; R. I., W. R. White, Providence; S. C., W. Peyre Porcher, Charleston; Tenn., T. J. Happel, Nashville; Texas, D. R. Wallace, Waco; Vt., D. C. Hawley, Burlington; Va., Bedford Brown, Alexandria; Wash., C. L. Flannigan, Olympia; W. Va., G. A. Aschmen, Wheeling; Wis., Jas. T. Reeve, Appleton.

On Incorporation.—R. Harvey Reed, Mansfield, Ohio; J. F. Hibberd, Richmond, Ind.; Irving A. Watson, Concord, N. H.; N. S. Davis, Chicago, Ill.; W. B. Atkinson, Philadelphia; W. T. Briggs, Nashville, Tenn.; W. K. Sheddon, Williamsport, Tenn.

TREASURER'S REPORT.

DR. RICHARD J. DUNGLISON, Treasurer, in account with the American Medical Association, for Fiscal Year to April 30, 1891, inclusive.

Dr. 1890.	
May 24. To cash balance reported by Treasurer at Nashville meeting	\$4,483.53
May 24. To balance, office of publication, at end of fiscal year	666.93
May 24. To dues collected at Nashville meeting \$3,765.00 less exchange	3,758.00
To balance of unexpended appropriation for stenographers	25.00
1891.	
April 30. To dues collected to date	10,045.00
April 30. To amount received at office of publication of Journal to end of its fiscal year	14,464.04
	\$33,438.50

Cr. 1890.	
June 2. By cash paid Dr. R. J. Dunglison, Treasurer, expenses of travel, etc., postage, telegrams and expressage	125.85
June 4. By stamped envelopes	\$7.20
June 5. By Dr. W. W. Potter, Chairman Section of Obstetrics, etc., expenses	10.25
June 5. Dr. G. C. Savage, Chairman Finance Committee, Nashville meeting, rental and printing	273.60
June 5. To C. F. Pollak, Index Clerk	10.00
June 5. By dues refunded	15.00
July 20. By Ward & Barnitz, printing	10.50
July 20. By rental of P. O. box	3.00
July 20. By stamped envelopes, expressage, telegrams, stationery, postage	38.06
July 25. By Wm. F. Fell & Co., printing	5.00
July 25. By Wm. F. Fell & Co., printing for Permanent Secretary	18.00
July 25. By stamped envelopes	8.00
August 9. By Dr. J. H. Musser, Chairman Section of Practice, expenses	19.00
September 5. By stamped envelopes, stationery, postage, duty on book	52.30
October 24. By Wm. F. Fell & Co., printing for Permanent Secretary	5.50
October 30. By Ward & Barnitz, printing	8.25
November 15. To postage, stamped envelopes, stationery, collector's commissions, expressage	33.02
November 15. By rental of P. O. Box	3.00
November 15. By Dr. P. O. Hooper, President of Board, draft on Treasurer, for expenses of Trustees of Journal to meeting of Board at Washington	337.50
1891.	
January 19. By Ward & Barnitz, printing	7.50
January 19. By rental of P. O. box	3.00
April 16. By Wm. F. Fell & Co., printing for Permanent Secretary	21.75
April 25. By Dr. W. B. Atkinson, Permanent Secretary, postage, telegrams, stationery, expressage, travelling expenses to date	146.35
April 27. By cash City Trust, Safe Deposit and Surety Co., premium for bond of Treasurer, as per resolution of Board of Trustees	50.00
April 29. By postage, stamped envelopes, stationery, collector's commission	39.59
April 29. By Ward & Barnitz, printing	5.85
April 29. By rental of P. O. box	3.00
April 20. By Drexel & Co., collection expenses on drafts	111.70

April 29. By Farmers & Mechanics National Bank, exchange on checks deposited during fiscal year	24.15
April 30. By Ward & Barnitz, printing	13.00
April 30. By paid office of publication of Journal since last annual meeting	\$,151.50
April 30. By expended by office of publication of Journal during its fiscal year	14,634.57
April 30. By balance in treasury	\$8,664.81
April 30. By balance in office of publication of Journal at end of its fiscal year	\$762.40
	9,427.21
	\$33,438.50

WASHINGTON, May 5, 1891.
This certifies that we have examined the accounts and vouchers of R. J. Dunglison, Treasurer of the American Medical Association, and found the same properly vouched and accurately cast, and that the balance in the treasury is \$9,427.21.

ALONZO GARCELON,
JOHN V. SHOEMAKER,
D. E. NELSON,
Auditing Committee.

MISCELLANY.

CHANGE OF ADDRESS.—Prof. John B. Hamilton has removed from Washington, D. C., to the Sherman House, Chicago.

REMOVAL.—Dr. E. A. Waggoner from Carrollton, Mo., to Burlington, Iowa.

THE SECOND TRIENNIAL SESSION OF THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.—*Circular No. 1.*—The Committee of Arrangements takes great pleasure in announcing to the members and invited guests that the arrangements are sufficiently advanced to assure the success of the Second Triennial Session of the Congress of American Physicians and Surgeons, which will be held in this city during the 22d, 23d, 24th, and 25th of September, 1891.

A number of distinguished physicians and surgeons from abroad have accepted the invitation to attend, among whom may be named Mr. Thomas Bryant, Mr. B. E. Broadhurst, Mr. A. E. Durham, Mr. Reginald Harrison, Surgeon General Sir W. E. McKennin, Mr. U. Pritchard, Mr. F. Treves, Sir William MacCormac, and Dr. James G. Gloyer and William M. Ord, of London, England; Drs. McCall Anderson and W. T. Gairdner, of Glasgow; Mr. E. H. Bennett and Professor Cunningham, of Dublin; Professor John Chiene and Dr. J. Battey Tuke, of Edinburgh; Professor H. Krause and Dr. F. Seeby, of Berlin; Professor Curschmann, of Leipzig; Professor Hoffa, of Wurzburg; Professor Kuhne, of Heidelberg; M. Emil Inval, M. E. Landolt, and Dr. Pozzi, of Paris; Dr. A. Musso, of Turin; Dr. Von Mozengeil, of Bonn; Dr. Lowenber, of Paris; and Dr. Rafail Lavista, of Mexico.

The sessions of the Congress will be held in the Main Hall of the Grand Army Building, 1412 and 1414 Pennsylvania Avenue, from 3 to 6 P.M., daily.

The President's Address will be delivered in the Lecture Hall of the National Museum, Wednesday, September 23, at 8 P.M., followed by the Reception of the President, from 9:30 till 12. Order of Executive Committee. The Army Medical Museum will be open the same evening.

The sessions of the Societies will be held according to

the programmes of each, respectively, in the places as follows:

American Surgical Association, Main Hall, Grand Army Building, 1412 and 1414 Pa. Ave.

Association of American Physicians, Hall No. 1, Grand Army Building, 1412 and 1414 Pa. Ave.

American Climatological Association, Hall No. 2, Grand Army Building, 141 and 1414 Pa. Ave.

American Gynecological Society, Lecture Hall, Columbian University, 15th and H Sts. N. W.

American Laryngological Association, Parlor A, Arlington Hotel.

American Neurological Association, Parlors 182 and 183, Arlington Hotel.

American Orthopædic Association, New Reception Room, Arlington Hotel.

American Otological Society, Ladies Parlor, No. 1, Arlington Hotel.

American Ophthalmological Society, Ladies Parlor, No. 2, Arlington Hotel.

American Physiological Society, Parlor 181, Arlington Hotel.

The officers of the American Dermatological Association and the American Association of Andrology and Syphilology have made their arrangements with the Shoreham for places of meeting.

Office of Registration, Parlors 1 and 2, Arlington Hotel. From this office the mail of members and guests will be distributed, and the city residence of each member or guest can be ascertained.

The Association of American Anatomists will meet in this city during the sessions of the Congress, and will occupy Hall No. 3, Grand Army Building. The American Pediatric Society will meet here September 23, and 24, in the Lecture Hall of Columbian University, 15th and H Streets, N. W.

The Congress will be composed of the members of the societies and invited guests.

A registration fee of five dollars will be required of every member of the constituent societies who may register; invited guests will not pay the fee. Order of Executive Committee.

Participating societies can "accredit visitors to the Congress, who shall pay the registration fee, but shall not be privileged to participate in the deliberations of the Congress." Order of executive Committee.

A copy of the transaction of the Congress will be sent to each person who may register.

Only those who may register, invited guests, and ladies accompanying them, will be admitted to the Reception of the President.

Secretaries of constituent societies are requested to supply this Committee with the names and addresses of "accredited visitors."

The evenings of Tuesday, September 22, and Thursday, September 24, are left to the societies.

Members of the American Surgical Association and of the Association of American Physicians will conjointly entertain their foreign guests at dinner at the Arlington Hotel, Thursday, September 24, at 8 P.M.

The American Gynecological Society has also arranged

for a dinner at the Arlington Hotel, Thursday evening, September 24. The American Pædiatric Society give a dinner September 24.

Other societies that intend to entertain their foreign guests are requested to communicate with this Committee.

Arrangements are in progress to secure reduction of railway fares. As soon as completed, the information will be communicated to each member and "accredited visitor."

The Arlington Hotel offers accommodations at the rate of \$4 per day, and the Hotel Arno offers rates "on the American plan at \$3 and \$4 per day, on the European plan, \$1 each per day. Exclusive use of bath, \$1 extra."

A blank certificate of registration will be sent to each member and "accredited visitor." The Committee requests each person receiving such certificate to fill the blanks and return it, with the fee, to Dr. John S. Billings, Treasurer of the Congress.

The American Pomological Society, and perhaps other societies, will meet in this city September 22-25. The Committee therefore suggest to the members an early arrangement for hotel accommodations.

Inquiries relating to railway fares must be addressed to Dr. S. S. Adams, 1632 K Street.

A complete roster of membership of the Congress has been prepared, with post-office address and society to which each member belongs.

The Committee will take pleasure in answering any inquiry relating to the local arrangements of the Congress.

SAMUEL C. BUSEY, M.D., *Chairman*.
1545 I Street N. W.

Washington, D. C., June 24, 1891.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from June 20, 1891, to June 26, 1891.

Major Julius K. Patzki, Surgeon, leave of absence on surgeon's certificate of disability, granted in S. O. 99, May 1, 1891, from this office, is extended two months on surgeon's certificate of disability. By direction of the Acting Secretary of War. Par. 15, S. O. 142, A. G. O., June 22, 1891.

Capt. William C. Borden, Asst. Surgeon, will, upon the final abandonment of Ft. Davis, Texas, report in person to the commanding officer, Jackson Bks., La., for duty at that post. By direction of the Secretary of War. Par. 4, S. O. 139, A. G. O., June 18, 1891.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending June 27, 1891.

Surgeon J. H. Hall, from Naval Station, New London, and to Naval Hospital, Chelsea, Mass.

P. A. Surgeon L. W. Atlee, from nautical school ship "Saratoga," and wait orders.

P. A. Surgeon J. M. Steele, ordered to nautical school ship "Saratoga."

Asst. Surgeon G. A. Lung, ordered to Naval Station, New London, Conn.

Asst. Surgeon J. E. Page, from Naval Hospital, Mare Island, and to the "Independence."

Asst. Surgeon M. R. Pigott, from U. S. receiving ship "Independence," and to Naval Hospital, Mare Island, Cal.

Asst. Surgeon J. G. Field, detached from U. S. S. "Omaha," and granted three months' leave of absence.

Frederick Gratton Brathwaite, of Stamford, Conn., commissioned an Asst. Surgeon in the Navy June 22, 1891.

ADDRESSES.

PRESIDENT'S ADDRESS.

Before the Annual Session of the State Medical Society of Connecticut, June 8, 1891.

BY M. STORRS, M.D.,
OF HARTFORD, CONN.

Gentlemen of the Connecticut Medical Society and Honored Delegates: I congratulate you on this, the ninety-ninth convention of the Connecticut Medical Society.

The year which has brought us to this epoch in the history of this society has been one of remarkable interest and activity in medicine throughout the world. Other years may have seen as much of substantial progress, but the year now ending has been marked by greater enthusiasm and has never been surpassed in close and critical investigation. Medicine has been so brilliant in its possibilities, so inspiring in its hopes, that it has caught the eye of a sympathetic world that has hourly and eagerly watched for the tidings, heralded from the laboratory and the clinic.

The year was ushered in by a strange pandemic disease, going over the continents and crossing the seas with the swiftness of light. It challenged etiological recognition. It eluded the scrutiny of the myriad of lenses focused upon it. It demonstrated to the biologist that there are causes of disease more subtle and imponderable than the microbe.

The unprecedented gathering of physicians at the international congress at Berlin was a prominent event of the year, both in itself and because it became in the public mind linked with the great discovery of Koch. For a time a feeling of disappointment clouds the public mind, and clinical and preventive medicine must have a patient waiting. But sympathy is with the discoverer, and the hope still abides that many now incurable forms of disease will be prevented or ameliorated. Subjects generic, but in a certain sense subsidiary to the great discovery announced by Koch, the contagiousness of phthisis, the relation of bovine to human tuberculosis have been warmly discussed. Tremendous interest attaches to every feature of that disease that carries off one-ninth of the human family.

The anti-vaccine war has been carried on in England with more zeal than ever. Edgar Crookshanks, of London, authority on bacteriology, has published his views, being similar to those of Creighton in the *Encyclopædia Britannica*. The contest has been carried to Parliament and several reports have been made. But Jenner is not dethroned.

But we must close the retrospect of the year. Standing here under the lengthening shadows of the closing century of our history we had it in our minds to take some theme appropriate to its departure. But we turn aside from this, as well as from all the exciting themes of the day, and ask you to consider the

HEALTH OF THE SCHOOLS.

The health of the schools is a difficult matter to determine, as many conditional factors enter into the calculation. Probably no one, if asked the question as to the actual sickness or physical or mental impairment in the schools of this state, could give any answer approximative of the amount. And yet there are men who are well posted in health matters who can tell just how many have died in the State and of what and where they died, the difference being that those to whom we refer have a plan and method of getting the information they desire through their regular system of reports, while those having charge of the schools have no systematic health inspection or supervision, and hence scanty or imperfect records. If we consult the district or school register it gives the attendance and non-attendance, but does not indicate in regard to the latter class whether they were absent from sickness or otherwise.

Parents know something about their children. They have occasion to speak of their ailments, of their pale appearance and languid condition, headache, loss of sleep and appetite. But they have made no satisfactory investigation, and know very little about the school-house or methods of study.

The board of school visitors who have supervision of the schools and, as local officers, come very near to the scholars, rarely make an inspection in the direction of health unless some epi-

demic is prevailing, nor do they make any special record or report of their inspection.

From the school board we go to the State Board of Education, the general headquarters of the schools. The items of interest from every district are at last supposed to center here and are tabulated even to the planting of a tree, blanks having been sent out to be returned with all the specified details. Here may be the place to find the facts of disease if any have existed. But in all the reports of the State Board for the last twenty-five years we scarcely remember to have seen, with one or two exceptions, anything especially relating to the health of the schools. Great irregularity of attendance is reported from many of the towns and much deplored, but nothing to show how much of this non-attendance was due to ill-health, though as a matter of fact, sickness is known to have prevailed at the time to the extent of making the discontinuance of the school necessary.

We come at last to Boards of Health, local and State. A valuable report is issued annually by the State Board which the State might well afford to distribute largely among the people. It makes valuable suggestions to the towns. It formulates inquiries and in turn gets responses from physicians and others. It discusses sanitary subjects, investigates local and epidemic diseases. There is almost no end of good work that it is doing, but we fail to find that school hygiene or school sickness has ever been to any extent mentioned or scientifically considered. A model school-house has been described; typhoid fever in Yale some three years ago was investigated and reported. But no systematic and thorough study of the health of the schools has been carried out, though there has been a suggestion that such an attempt would be made at some future time. Our State Board of Health may share, perhaps, the feeling of the local boards, that our schools are under the control and guidance of other men and other boards, and that it would be an intrusion to invade their precincts.

Again in our search we turn to the code of school laws to find some sanitary or health enactment, but out of the three hundred sections of the school laws nothing pertaining to the health of the schools except the enactment which empowers the Board of School Visitors to compel vaccination. The State constitution does not make any reference to the schools, except to make provision for the school fund. Neither do the proceedings of this society, which is the general organized health custodian of our State, show that any discussion or investigation has been carried on in this line except in 1887, when President Comings, in his address on nervousness, gave some timely utterances on the effects of over-pressure from study.

So far our inquiries concerning the health of

the schools have been futile. But the inference which might be drawn, viz., that there is no sickness in the schools, to our mind is not so strong as the suggestion which arises that the schools require that a more thorough inspection should be made in sanitary and health matters, to see whether or not any sickness exists.

It is a principle followed in all economic, social and civil interests to first investigate and get the data and facts. It is as much, or more, the object of this address to show the necessity of this work as to bring before you the evidence or the amount of ill health.

In other countries and in other States some inspections have been made, and there have been some partial inspections in our own State. In 1878, after the reports of the examinations for near-sightedness which had been made in the public schools of Europe and this country were published, the school visitors of Hartford caused an inspection to be made in two schools in this city, with the following result. In one examined by the late Dr. J. A. Steven 21 per cent. of the pupils were myopic; in another inspected by Dr. W. T. Bacon, of this city, 20 per cent. were found in like condition. When the prevalence of that change in the form of the eye conditioned largely upon badly constructed school rooms, affecting the amount and direction of the light, was ascertained by an inspection, its causes were inquired into and the disease has become much less prevalent. I visited, during the year, a new school house in another city of this State and the light was abundant, exceeding somewhat the amount required,—one-fourth of the floor space. It was stated that in the room having the oldest pupils no case of myopia was to be found, a confirmation of the good results growing out of inspection.

Dr. E. K. Root, in his report as consulting physician in the Normal School Gymnasium, says: "Out of a total of over five hundred and eighty pupils examined, one hundred and eighty-six—nearly one in three—show slight lateral curvature, elevation of one shoulder, stooping carriage, or unequal prominence of shoulder blades. Slight lateral curvature with elevation of the right shoulder was observed in a number of instances, and was undoubtedly due to faulty position at desk work, or badly arranged school desks and benches. The majority, however, show no constant change that can be ascribed to any one cause. Their condition is the result simply of lack of symmetrical exercise of both upper extremities during the period of growth."

Sir John Forbes says: "We lately visited, in a large town, a boarding-school containing forty girls; and we learnt, on close and accurate inquiry, that there was not one of the girls who had been at the school two years that was not more or less crooked."

These inspections made with reference to these deformities are frightful, and in connection with them I give the views of Dr. W. Arbuthnot Lane, Assistant Surgeon to Guy's Hospital and Surgeon to the Children's Hospital, Great Ormond street, London, who makes some timely remarks as to the condition of these deformities. "In the young subject the rate of growth of any portion of an epiphysial line varies inversely as the amount of pressure it transmits. In other words, if one-half of an epiphysial line transmits habitually an amount of pressure which is greater than normal, the amount of bone which it develops is correspondingly less than that normally produced. If, on the contrary, the other half of the epiphysial line is subjected habitually to a subnormal pressure, the amount of bone developed by it is proportionately greater than the normal. In all the resting postures the mechanism of the skeleton is such that one portion of a growing line is exposed to an abnormal pressure, while another portion is exposed to a much less, or even subnormal amount of pressure. The frequent assumption of a single attitude of rest, not corrected by suitable variations in the attitudes of activity and rest, results finally in a progressive alteration in the form and function of the bones and joints." And we may add when these bony surfaces, changed in form, become dense and eburnated, they cannot be restored by treatment, either mechanical or by exercise, but the form of the skeleton is lost forever.

Dr. Root describes the majority of these deformities, much more common to girls, to the "lack of symmetrical exercise of both upper extremities." Dr. Lane would include also the lack of symmetrical attitudes of rest.

This opens for consideration not only the question of exercise, but turns attention to the school seats in use, and upon which we have, as a country, prided ourselves. But Mr. Northrup says: "The improved seats (the American) are recommended mainly as they favor erectness of posture. But it must be admitted that with poor seats, sometimes only deal planks, the posture of pupils in the French, Swiss and German schools is far better than that of American youth in our best furnished houses."

The American seats make a good furnishing for the room. But the schools are graded by scholarship rather than by size. In almost any of the school rooms we will find some older and larger pupil in a cramped position, and some smaller one with feet dangling in the air. If the deal benches are better adapted for combining "attitudes of activity with attitudes of rest," and varying them in character, then deal benches are the best seats.

We have offered these inspections as illustrations. Inspection, thorough and scientific, made in any direction would give unexpected results.

As a specimen of a general inspection I refer to one made in Sweden and Denmark, two countries having the lowest mortality rates of any in Europe or in this country, and, after England, having the highest surplus of the birth over the death-rate. I quote from an abstract of a paper read by Prof. Axel Key, of Stockholm, at the International Congress at Berlin, and which paper attracted great attention in the Congress. He states that it was found in the schools of Sweden, by a very careful inspection, that out of 15,000 boys of the Swedish schools 40 per cent. were ill in one way or another. In the preparatory schools 17 per cent. in the lowest classes, 37 per cent. of the next higher class, and 40 per cent. of the highest class showed illness. Similar conditions were found in Denmark. With regard to the health of girls the state of things was frightful. The percentage of disease in the 3,000 girls mentioned above was sixty-one, out of which 36 per cent. suffered from chlorosis, as many from habitual headache, 10 per cent. from curvature of the spine, and 5 per cent. from scrofula.

"These conditions," said Prof. Key, "were no doubt due to over-pressure." He concluded by suggesting that uniform international investigation should be made into the whole subject."

Our personal knowledge in regard to the sickness of the schools is not statistical nor numerical, but from a considerable amount of observation we can confirm in general the truth of the inspections which have been presented. We meet with sicknesses and prevailing diseases which have a direct reference to the schools, either to some unsanitary condition of the school-house, to the peculiarities of the school age, methods of study or to bad or indifferent management of the schools.

It is evident that inspection close and thorough will reveal disease. The same method if used will disclose the causes of many of them. We apply it to the

SCHOOL-HOUSE.

There have been great improvements in the construction of the school-house in the last thirty years. This is especially true of the larger and wealthier towns. Before this era, too often the school-house was a rude and plain structure, devoid of any architectural merit. Some of the best school-houses now take rank with the finest public buildings. In the rural and depopulated districts economy governs, and the school-house is hardly a fitting expression of any commensurate interest in education. But the graded schools have become institutional centers and an architect has no small task in many instances to devise plans equal to the wishes and expectations of the district and equal to the generous appropriation made. All this to a certain extent measures the popular interest in education.

Within the last few years my attention has been called to many of these school buildings both in and out of the State, and to some abroad. I shall refer for the most part to those in this immediate vicinity as best known to me and from their general standing can in no way be said to be exaggerated illustrations.

Mr. B. G. Northrup, the late Secretary of the State Board of Education of this State, having observed the schools of this country pretty extensively, and those in Europe, states in one of his later reports that we need not shrink from the comparison of our school-houses with any European country, and he also adds that no city of its size in America can show better school edifices than Hartford. As Mr. Northrup makes those of Hartford the best in the world for any place of its size, it is quite safe to assume that there are none better in the State than those in Hartford, and especially safe in this assumption as since Mr. Northrup's statement was made many have been reconstructed and some new ones built. My observation, as far as it goes, agrees with Mr. Northrup's statement. But I now introduce some facts concerning these same Hartford school houses taken from a report of the Board of School Visitors of this city in 1889, after quite a thorough general inspection had been made. As the report is one of length I refer to it without giving the exact language.

The Board says that no school building was found in a perfectly satisfactory condition; something unsafe or unsanitary was found in all of them. Many of them were unsafe in the matter of fire from their heating arrangements and in the event of burning there was no ready way of escape. Others had tile soil pipe within the building with broken or open joints and unventilated; foul and unsanitary water-closets within the building and, if outside, not sufficiently separated from the school-house; empty traps, crowded and insufficiently ventilated rooms. Insufficient heat and light, flues which were dead, or if they worked at all, worked in the wrong direction, poor locations. One large central and wealthy district had all these defects and more. The school-board says of this school-house, "Words fail us in speaking of this school building. It is thoroughly unsafe and out of order from beginning to end."

Of one school-house Mr. Northrup says: "I do not know where else in the world can be found a school-house for the children of operatives surpassing it." The committee found this school-house to be a four story building, entrance upon the middle of each side into a common hall from which ran a central stairway to the top of the building. Underneath this lower hall through which all the children passed in going to and fro was the furnace. In the basement at either end were the water-closets or water troughs or latrines,

and these were adjoining the hot air chambers. The committee recommended the removal of the latrines and the erection of a fire escape.

Mr. Northrup honors another school edifice by putting an engraving of it in his report. The acting school visitor of the town at that time informed us that he had seen in this building seventy-five scholars crowded into a room fifteen by twenty feet. That does not now exist. Such are some of the faults of the model buildings in this fair city so distinguished for its school edifices. There is no doubt but that a thorough inspection of school-houses in any city or town of the State would reveal the same or a worse state of things. It was not my purpose to speak of any special points which this inspection brought to light, although many of these conditions cannot exist without being the fruitful cause of disease. We pass, then, over the site or locations of the buildings and the condition and use of the basement stories, mostly occupied with the heating apparatus and as play rooms for the children, the plumbing worn out in the older buildings and imperfect in others, the cause of filth diseases in some districts. More attention however, is being given to sanitary plumbing, and a healthy fear has arisen in the public mind for blood poisoning. All this has been brought about by sanitary study and efforts of the Boards of Health. But there are one or two items in this part of our subject upon which we wish to remark.

VENTILATION.

The most serious defect found in the schools under examination was the imperfect ventilation. Much attention has been given of late to this subject, but among the masses of the people the fundamental principles are not understood, and our architects and civil engineers have not come to any consensus of views as to the best methods to be employed. It is my deliberate opinion that bad ventilation has more to do with the impaired health of the schools than any other one thing. Most of the Hartford schools depend upon natural ventilation. Only one school has mechanical appliances and two or three have partial aspiration. The impure air escapes through flues, but they are insufficient in size and badly located. Hence resort is had to open windows and doors to obtain any fair degree of ventilation. The general result is that there is no system.

It would exceed our limits to discuss the question of a perfect system. But such a system is possible. Let the dimension and requirements of a school-house be known, the amount of fresh air needed for each scholar per minute, the temperature of the air on admission, temperature required for the room, rate of air currents by actual air tests, the highest allowable limits of carbonic acid, no open doors or windows. A con-

tract including all these specifications could be made with a guarantee for its fulfillment.

No air should be used for respiration that has over seven vols. of carbonic acid to ten thousand of air, ordinary air having four vols. The schools to which Mr. Northrup refers cannot keep, by the ventilation provided, the carbonic acid down to thirty vols. Open windows are resorted to, but they are uncertain and unsafe. Uncertain because they disturb the flue ventilation and should the external and internal temperature be alike they would afford little ventilation, and are unsafe because if there is an exchange of air, dangerous draughts are occasioned. To this poisoned air of respiration is added the natural excretions of the skin, the emanations from the uncleanness of the body and clothing. Some children bring with them the characteristic odors of their homes, the fumes of the kitchen, the sickly smell of unventilated rooms. Besides, the air of the school room is impregnated by many of the odors of disease, the discharge of ulcers, decayed teeth, bad throats and fetid eructations. The school room thus becomes the mart of the district, where the germs of disease and putrefaction find their best place for development and dissemination. People have come to feel the imperative need of attending to sewerage to carry off the fecal and urinary wastes so as to prevent accumulations and hurtful effluvia.

It is well to bear in mind that as much weight of matter emanating from the lungs and skin is to find its way out of the flues and windows, as goes downward into the earth by way of the water-closets. We estimate from data on this subject, that a school-room of fifty pupils would throw off in the form of cutaneous and pulmonary exhalation, in one month of five hours each day, 750 lbs., which contains much putrescible matter, and in rooms deficient in ventilation this is precipitated, and gives in its decay the peculiar odor of the badly ventilated rooms. These respiratory impurities furnish the best possible conditions for the growth and dissemination of microbes. "Carnelly found in dirty school-rooms with the so called natural ventilation, in the same volume of air, nearly 2,000 living bacteria, while in mechanically ventilated schools there were from thirty to three hundred." Children from homes infected with germ diseases, consumption, scarlet fever and diphtheria, will poison the air of a room unless the floating germs are carried off by fresh currents of air.

The air space allowed for each child in the schools in Hartford is 225 cubic feet, with the air to be changed three times per hour. This is about one-third of the amount needed. But the Board of School Visitors has been asked to approve plans for a new building where the cubic space did not exceed 45 cubic feet per scholar. This is a very good illustration of local school

management. Boston seems to be about as badly off, judged by the figures of the Report of the Chief of District Police. "In 1889, 163 school-houses in Boston were inspected, and 146 are without any modern or efficient means of ventilation, being dependent upon the old-fashioned shafts in the walls, aided here and there by small apertures through the external walls, all of which are too feeble to be called ventilation."

People do not sufficiently realize the hurtful nature of impure air—how it vitiates the blood and interferes with the circulation, accumulating in the right heart and lungs, and produces asphyxia in some degree; undermines the constitution; lays the foundation for serious organic disease, preëminently consumption. It is estimated by competent observers that 40 per cent. of all fatal diseases are due directly to impure air.

Dr. Cornelius Black, of London, in answering the question, "Which side of the heart is the more frequently affected by disease?" says that the carbonic acid, rendering the blood impure, debilitates the right side of the heart, and the bad air of school-houses, as now constructed, causes a dilated right heart, and tricuspid incompetency.

I know a young lad, robust and healthy, fond of school, but the air of the school-room gives him a headache which results in vomiting, unless he goes into the open air.

SAFETY FROM FIRE.

The School Board found seven buildings out of eleven unsafe for want of sufficient exit in case of fire. In these there was only a single possible way of escape, and that was from the centre of the building, and generally directly over the furnace or boiler, which was in the basement. Only two of the schools have the heating apparatus outside of the building.

This is a very important matter. In this country the destruction of school-houses, asylums and hospitals, by fire, being no infrequent accident. Even the alarm of fire among school-children is accompanied with panic, and often with serious loss of life. Safety demands that these buildings should be practically fire-proof, at least the corridors and stairways. The latter should be constructed of iron or stone, the wainscoting being of brick or tile. It requires some experience with the fearful calamity of fire to give emphasis to any words upon this subject. A few years ago, when the Hartford High School building was destroyed, though no lives were lost, the fire occurring in the night, yet it was easy then to get an appropriation for a fire-proof building. It has been in my experience to have witnessed some of the larger battles in the late civil war. I have seen the field covered with the slain; but the sight was not so sickening or revolting as when, in after years, in another State, I witnessed a long

row of little school-children burned or suffocated to death. The battle field told the story of heroism, of undying devotion to one's country, and the great sacrifice that loyal hearts were ready to make for the preservation of the Union, and the restoration of National authority. All this would live and go down through the ages in song and in story—but the smouldering ruins of the school-house and the little charred bodies only told the old familiar story of carelessness, indifference or greed, all to be forgotten in the passing of a day.

PECULIARITIES OF AGE.

There are certain conditions of age, growth, periodicity, and peculiarities belonging to the school age, affecting health. We designate the school age as from 5 to 15 years of age. This period has the lowest death-rate of any, being seven per thousand, while for all lives the death-rate is from eighteen to twenty per thousand, and is in great contrast to the preceding period of infancy, which, according to the census of 1880, in the first year of life has a mortality of 170 per thousand, and in the large cities the rate is much higher.

Of the deaths of school-children, the Pennsylvania State Board of Health shows that at least 30 per cent. were from diseases regarded as preventable.

But notwithstanding the low death-rate of the school age, there is on the other hand a high rate of disease, not accounted for by the special diseases of children, and which might be prevented by better sanitary conditions of the schools, and by a better appreciation of the laws of growth and development of childhood—preventing future invalidism. A child who rests upon the sacro-iliac synchondrosis of one side before there is a growth of the articulating surfaces, will develop lateral curvature. So a child, at the time when the peripheral nerves are comparatively larger than the nerve centres—when the spinal cord predominates over the brain, or the medulla oblongata possesses functional superiority, who should attempt the higher cerebral functions, will easily have exhaustion of the brain, ending in some form of neurosis or in cerebro-meningitis. The natural but unexplainable periods of retardation must be recognized and studied.

Prof. Key, before quoted, has made accurate observations concerning the law of growth and retardation in the schools of Sweden and Denmark. He reports on the measurements and weights of school-children which had been taken in Sweden and Denmark during the last ten years. The results obtained in 15,000 boys and 3,000 girls, showed that in the seventh and eighth years the increase in stature and weight was very marked in boys. Afterwards, however, a retardation occurred which lasted to the fourteenth year, in which a rapid increase of growth again

occurred. This increase lasted up to the seventeenth year; it was most marked in the fifteenth year; the least increase in the preceding period was in the tenth year. The increase in growth was first in stature, and it was not until later that it also showed itself in the weight. The increase in weight lasted up to the seventeenth year, when the bodily development was complete. In girls the case was somewhat different. The decrease in growth after the eighth year was not so marked as in boys; in the twelfth year it had already given place to a great increase in height. The increase followed that of height, but exceeded it in the fourteenth year. In the seventeenth and eighteenth years the increase in height was but slight, the increase of weight, however, fell nearly to zero in the twentieth year. At that period growth seemed to be completed. Prof. Key says that the diseased percentages were highest in the period of retarded growth. And in the time of the greatest increase of growth they were the least.

Sometimes we are consulted because a child in these specified periods does not grow—is stunted; and again when a child is growing rapidly. In the one case there is apprehension of some disordered condition, and in the other that there will be.

TEMPERAMENT.

This is a natural condition, but is affected by school life. By the older physiologists much that is fanciful has been written concerning temperament. The kinds and combinations have been minutely described. This much is true, that there are certain constitutional differences in persons which grow out of the variety of relations and proportions existing between the constituent parts of the body; and which, to a certain extent, influence the dispositions and characters of men, and have a marked influence upon the functions of every part of the organism. Some men have a happy disposition, and, like Joseph Priestly, can go through life always cheerful, though suffering reproach at the hands of their fellow men. But for the many, the disposition is largely formed or fashioned in childhood. The parent or teacher can make or spoil the child in this critical age. They have an influence in this direction equal to or greater than the bile, lymph, or blood, even, to impart a feeling of felicity, or gloom and depression. Felicity causes the heart to beat full and strong, brightens the eye, expands the chest, aids digestion, gives to every movement grace and steadiness. The old belief that pupils must have pain and suffering to acquire knowledge is exploded. Herbert Spencer formed his educational system quite largely upon good feelings. If we cannot go so far with him, yet we do not err in making the school and studies agreeable, and so healthful.

STUDY.

A full comprehension of the effect of study on the health requires a knowledge of the laws and limitations of the mental organism itself, and the union of this entity with the physical organization. The right conception of study—of education, is the systematic and symmetrical growth and development of mind and body. Such study produces healthful results, and is expanding to both mind and body. Study is not incompatible with health. It is a well-known fact that those who have devoted their lives to hard study have had a greater longevity than any other class of men. Take as an illustration the Presidents and Professors of Yale College. Of the nine Presidents who have died the average age was 70 years, and of forty professors the average age was 65¹/₃ years, and the average of all graduates of Yale in the eighteenth century was nearly 62 years. This is indeed a remarkable record.

But the mind requires a natural development of its powers, the faculties to be expanded in harmony with each other. Some teachers not only seem to look upon the mind as an entity to be handled separately from the body, but that any faculty can be cultivated *ad libitum*. This is always at the risk of an abnormal mental development and of a general impairment, initiated from a local mental strain or over-doing. That process of education called memorizing is useless and hurtful. It not only takes away from the fullness of other mental processes, but may imperil the whole organ.

Dr. B. N. Comings, in his address to this society as President six years ago, on nervousness, had examined this whole matter of over-study very thoroughly by actual inspection and by means of circular letters, and says as a result of his inquiries, that "fully one third of the children in our graded schools suffer seriously from over-work in their studies; then become nervous and irritable at home, lose their appetites, and run down generally during term time. Nervousness is becoming a prominent characteristic. Diseases of the nervous system are on the increase."

Dr. H. P. Stearns, in his work upon "Insanity, its Causes and Prevention," in his admirable chapter on the influence of education, says in reference to the competition for prizes and scholarships, "from personal observation, I am satisfied that some of the brightest minds are essentially ruined for the accomplishment of any large work in life by such a course of conduct in their education, who, under some other course of management, in which these mental tendencies could have been better understood and guided, might have been saved; and that often these are minds with the best natural endowments."

Dr. Andrew Clark says, "I am a witness to the grave and sometimes irreparable mischief

done at schools and in working for competitive examinations." There is a large amount of medical experience recorded of the pernicious effects of undue study, long lessons, many studies, memorizing, competition, prizes, scholarship, etc. Every physician is meeting with cases of brain trouble from something vicious in the plan and course of study. Its range is all the way from brain weariness and nervous exhaustion to congestion and fatal inflammation of the brain or insanity. We have seen many such unfortunate cases, but it is difficult to convince the teacher or parent that study was an element in the case. They always ascribe the result to some accident, some blow or fall. Sometimes a slight injury may be the exciting cause of meningitis in one whose brain has been predisposed by over-excitement in study. We have not in this country reached that fearful condition indicated by this statement, taken from one of our journals which reads thus: "The statistics of suicide among school children in Prussia during the six years, from 1883 to 1888 inclusive, show that during that period two hundred and eighty-nine children took their own lives. Of this number two hundred and forty were boys, and forty-nine girls. In 29.8 per cent. of the cases no cause could be assigned; but as regards the others, fear of punishment or of the examinations, excessive ambition and insanity were found to be the inciting reasons. These figures are amazing and seem hardly credible."

Instead of this impulsive and tragic form of German or European insanity, our children may receive mental strains, which, like any other form of brain injury, is rarely fully repaired, and may end later on in mental incapacity or insanity.

Granting the European tendency to suicide, still it shows that the school system of Germany fails to develop the individual into a strong, independent and regulative character, and is a lesson from the older to the newer civilization.

The suicides in the whole of Europe, of boys and girls, amount to two thousand annually, and there seems to be an ethnological fact connected with it without any ethnological reason. For statistics show that the central area of European suicides is Germany and the borders of the adjoining States. But the German children in this country are not characterized by a suicidal mania. The Americans do not find, on the other hand, that the climate of Germany is depressing. We attribute youthful suicide in Germany, so far as the schools go, in part to study, excessive ambition, and to a fear of punishment. Such punishment cannot be meted out to the derelict and delinquent in this country. The European schools seem despotic. Children are punished for offenses, and in ways that would not be tolerated in this country. I visited in Lucerne a fine, large school in the country, where the humane,

sympathetic, philanthropic educator Pestalozzi was born. Here the teacher who was my guide seemed to take pride in showing me the dark dungeons in the basement where the scholars were confined for any misdemeanor. When visiting the University at Leipsic I was invited to visit the prison cells to see the names and the works of art inscribed on the walls by incarcerated students. The rector of the University holds over the students the power of life and death.

AGE AND TIME OF STUDY.

A child is never too young to learn, but too young for a school of training before 7 or 8 years of age. The soft pliant brain has not steadfastness enough for reflective processes and soon tires of its perceptive glancings. I do not believe that the kindergarten furnishes the desideratum. It may be better than a poor home, but a poor substitute for a good one. The children in the kindergarten always look tired to me. Enforced play gives weary and sad looks.

The time of study in the schools does not at first sight seem excessive. But men who have distinguished themselves by brilliant learning have made short days. The teacher finds the day long enough. The discount and insurance clerks have but a little longer day. But it is the lessons that must be learned out of school, and the worry from lessons unlearned that cause most of the harm. The Boston schools forbid study out of school hours for the girls.

MANUAL AND INDUSTRIAL TRAINING AND EXERCISE.

In the early years of the schools, and now in the rural districts, the problem of exercise has been solved by the necessity of assigning to the children a certain amount of work. Our country abounds with frequent examples of the attainment of ultimate, physical, and intellectual success, where the conditions seem to have been a reciprocal influence of work and study, and such necessity has helped to develop manhood and a right feeling of the value and dignity of labor. But at the same time there ought to be mingled with this work and study the graceful and frolicsome games and amusements in which children engage. Sportive activities should make a part of every child's physical programme. Every one has seen the energy and zeal with which children carry out their playful sports. Such positive joy and satisfaction is highly invigorating to mind and body. But even this exercise should be within limits. A child may physically over-act and be unfit for mental improvement. Many parents and teachers have the impression that a child in danger of harm from excessive study may be sufficiently guarded from injury by an extra amount of physical exercise. This is entirely erroneous. There is only so

much nervous force and energy to be expended, and if it is exhausted mentally it cannot be regained by any demand made upon the physical energies. Mind and body must, to reach the highest results, be exercised proportionately and within certain and proper limits. We have seen cases of nervous exhaustion, disqualifying for any study, brought on by over physical exertion. Many of our higher institutions of learning, and some of our cities, are providing a gymnasium for regulative exercise, and industrial schools where some useful experience can be obtained in the right use of mechanical tools, etc.

We hurry to make the boy an adult, forgetting that the longer we can keep him young the longer will he live as a man. Exercise, either as work or play, as we have implied, must be within limits. We have seen by the sharp fierceness of competition in games, more frequently, injury of some physical organ, hernia or cardiac disease, and nervous exhaustion from exercise and study combined.

The natural system of instruction of Pestalozzi and Fröbel, the former taking the form of industrial training, or the older children, the latter of the kindergarten for the younger, is now sought to be applied to the children of intermediate ages, and to make manual and industrial training common to all the schools. How this shall be done is not our problem to solve, or how it will effect respectively the educational and economic interests of society. But whether the sum of expended physical and mental energy will diminish the vitality of the child is the question for our consideration.

MANAGEMENT.

We use this word in its widest sense; we mean to include the legal provisions made for our schools and the personal supervision given to them. Some of the characteristic features of the Connecticut schools go back to the early settlement of the colony. Some things that were wise and good then might be changed for the better now.

SANITARY LEGISLATION.

As has been intimated there has never been any sanitary legislation for the schools. They have been under the general supervision of boards of school visitors, and, as a part of the towns, subject to such health regulations as the local Boards of Health have adopted.

We have shown by the unsanitary conditions of the schools, by the amount of sickness which is preventable, that local supervision by school and health boards without special legislation has proved itself inadequate.

The Boards of School Visitors are not, as a rule, composed of men who have made health matters a study. The Health Boards are political appointments for the most part and sometimes made

in the interests of the opposition. In some few towns of the State they demonstrate the usefulness of the organization. But the present work of these boards through the State is forced upon our attention when we read what the secretary of the State Board has to say publicly of them. "The most prevalent heresy now existing among the health officials of the small towns of Connecticut is a deep-rooted skepticism as to the real need of their official existence. Because from year to year they do nothing, they take the unjust inference that there has been nothing to do, which is equivalent to saying that the towns over which they have sanitary supervision are now and have been for many years in such excellent hygienic condition as to be incapable of being improved. Another fallacy, closely related to the last, is the idea that a local Board of Health should be a passive rather than an active organization; that of its own volition it should never take cognizance of any unsanitary condition; that a Town Board should occupy the dignified position of a court of appeals, and take no action, whatever may endanger the public health, until the threatened danger is brought to its attention by other parties."

And it must be remembered that this picture is drawn of men who fail to do their common ordinary duty and does not refer to the schools, which almost as by common consent they wholly neglect.

Every argument that is good for sanitary laws for the factories of the State applies with equal force to the schools. The State in its wisdom four years ago enacted laws relating to the factories, and factory inspection. The same law, *mutatis mutandis*, would be a good one for the schools. Its short trial has demonstrated its necessity and can point to much good already accomplished. The report for 1890 shows that seven hundred and ten changes were ordered and that most of these orders were fully complied with. Many of these defects were found among the best managed factories in the State.

Massachusetts, the State which is now acknowledged to have the best schools in this country, one hundred years ago fully recognized in her State constitution the importance of State legislation and control of her schools. She has had a factory law, and since 1888 a sanitary law for the schools. The factory law has been a little longer in operation and shows more definite results. We subjoin the School Law of that State.

SECTION 1. Every public building and every school-house shall be kept in a cleanly state and free from effluvia arising from any drain, privy, or other nuisance, and shall be provided with a sufficient number of proper water-closets, earth closets or privies for the reasonable use of the person admitted to such public building or of the pupils attending such school-house.

SEC. 2. Every public building and every school-house shall be ventilated in such a proper manner that the air

shall not become so exhausted as to be injurious to the health of the persons present therein. The provisions of this section and the preceding section shall be enforced by the inspection department of the district police force.

SEC. 3. Whenever it shall appear to an inspector of factories and public buildings that further or different sanitary provisions or means of ventilation are required in any public building or school-house in order to conform to the requirements of this act and that the same can be provided without incurring unreasonable expense, such inspector may issue a written order to the proper person or authority directing such sanitary provisions or means of ventilation to be provided, and they shall thereupon be provided in accordance with such order by the public authority, corporation or person having charge of, owning or leasing such public building or school-house.

SEC. 4. Any school committee, public officer, corporation or person neglecting for four weeks after the receipt of an order from an inspector, as provided in the preceding section, to provide the sanitary provisions or means of ventilation required thereby shall be punished by fine not exceeding one hundred dollars.

SEC. 5. The expression "public building" used in this act means any building or premises used as a place of public entertainment, instruction, resort or assemblage. The expression "school-house" means any building or premises in which public or private instruction is afforded to not less than ten pupils at one time.

A comparison in Essex county of the factories and schools shows that the former affords eight times more cubic space per person than the schools, and had on the average only eight parts by volume of carbonic acid to twenty-one parts in the schools. These facts for the factory are cheering but for school sanitation disheartening. But the working of the Massachusetts school law, which was fiercely opposed at first, is now meeting with great favor, and will work changes in the schools that would not have been otherwise effected.

Connecticut is behind, but she has in operation the factory laws, and begins to note beneficial results. In this she has legislated for better ventilation, for good sanitary conditions of water-closets, fire-escapes, and many other things, and holds the person or corporation at fault responsible for all damage, besides a fine of not less than \$50 nor more than \$500. This is a statute law for the health and safety of operatives in the factories of this State. But why do the 135,000 operatives in the factories of the State need legislative protection more than the 161,241 children in our schools? The former are mostly of an adult age and capable of looking out for themselves, the latter are generally dependent and helpless, and to-day probably the school-houses, like those in Massachusetts, are not in as good a sanitary condition as the factories.

INSPECTION.

We have seen that when an inspection has been made, results have shown that it was needed, judging from the defects brought to light. But a thorough inspection, which is to go into all the details and to be a matter of record, must include

the good as well as the bad features of the school. Such a registration is made up of constructive details, working functions and the septic or aseptic conditions of the schools. This registration must be complemented by a complete health record of each day, which the school register can give. If scholars have ailments or are at home sick, the register will note the fact and their disease, so far as can be ascertained.

When these inspections and records have found their way to the central bureau they can be classified and compared, and it will be possible to determine where the defects are to be found, their nature and the best way of removing them; what diseases have prevailed, their causes and the prevention suggested. Such results can be tabulated, and will be of service in future comparisons.

The power of an inspection for good is very great. I have known the sickness in a school district first to have awakened suspicion of the school-house, which led to an inspection, and this to a warm discussion as to repairing or building. The first feeling was to repair, but as the facts of the inspection were canvassed, the outcome was a new school-house costing \$100,000. This grew out of an inspection.

We may call attention to the report made two years ago by the State Board of Education in one of the counties of this State. Probably the schools in that county were in no way different from those of any other county in the State, no better nor worse, and yet, so shameful was the condition found, so damaging the reports, that some threats were even heard in other counties if the work of inspection went any further. There is at first a feeling of repugnance to inspection, growing out of a suspicion of espionage or of meddlesome interference. But when it is known that the examination is in the hands of skilful and expert men, done legally and followed by good results, the prejudice soon yields. So in the examination made by the Board just alluded to, threats gave place to invitations to have the work done. Great good has resulted from that examination of a single county, though it was made along the educational rather than the sanitary lines.

It has always been a difficult problem how to conduct a school in reference to the infectious and contagious diseases. These diseases are practically narrowed down to the two diseases, scarlet fever and diphtheria. But if the prevailing type of measles is malignant, it will be put into the same category for management. Towns exercising ordinary care for their schools require notification, isolation and perhaps disinfection. If this were thoroughly done, these diseases would be to a great extent diminished. But it is not practiced over most of the State. Not long since, the largest city of this State made its difficulties in this matter public as follows: The committee on

schools sent a letter to the Board of Health, calling attention to the prevalence of contagious diseases in various parts of the city. In this letter they say "that the authorities show inexcusable laxity, and that they can cite instances that would indicate criminal negligence on the part of some physicians in the city. "The committee has evidence that there have been cases of scarlet fever where not only was no notice sent to the schools, but the death certificate was the first notice the health office received. Also that school children have been allowed to view the remains of children who have died of diphtheria. The President of the Board of Health said that some physicians were very neglectful, and one or two had been notified that, failing amendment, they would be brought before the courts. He also adds: "Scarlet fever has been propagated in several wards through the negligence of some of our physicians. Public funerals have been held, and no attempt has been made to guard against the spread of the disease. Some one was culpable, and it was the attending physician. A case in point came under my own observation only a short time ago. I learned," says he, "that a wake was to be held over a person who had died of diphtheria. I immediately notified the family of the true character of the disease. They were surprised, as the physician had not notified them that it was contagious. It is not only the young physicians who are negligent, but the old ones as well." Now the health officer says: "The only evidence we get of some cases of contagious diseases is the death certificate. In nearly all of the schools the principals and teachers know of the existence of contagious diseases. We have no way of preventing children from attending a funeral. I know of the case to which reference is made in the letter. I visited the place an hour and a half after the death. The parents promised not to allow anyone to see the remains. It seems that children did, however, and there is no help for it. Many principals, in their eagerness to have their schools make a good showing, allow children to return to the schools before it is safe for them to do so. I have heard of a number of cases where children who have been ill with scarlet fever have been allowed to come back to school before they were through desquamating."

It is seen that the school committee blames the authorities and the physicians, the President of the Board of Health blames the physician, and the Health Officer finds the principals of the schools and the parents at fault. But the moral of it all is, that the rule of notification and isolation is practically worthless.

But with notification, isolation and disinfection there must be more inspection—reasonable in kind and amount. Dr. Seibert, of New York, goes so far, in an article on the prevention of diphtheria and scarlatina, as to recommend that

the throats of all school children be examined every day by a physician, using the child's finger for a tongue depressor. It would require for New York City 300 examiners. Such inspection seems at least special and expensive. But New York has about 2,000 cases of diphtheria annually, and the same of scarlet fever, which means about 30,000 cases of sickness from both diseases, at a cost to the city, directly and indirectly, of millions of dollars. Such an inspection would cost New York \$300,000 annually. It might save hundreds of lives and a great amount of money. The inspection proposed for our schools would not be expensive, and would prevent these diseases at almost every point. It would travel on the lines that no foci or medium of contagion should exist, which is better than to be obliged to note their outbreak.

Many foolish customs and habits which now prevail would be set aside, as for example, we saw within a few years the children, clean and unclean, of a primary school, on leaving the room give the teacher a kiss. Now, suppose the first child was coming down with scarlet fever or diphtheria. No one can tell how many lives would be endangered. Good inspection would also keep out the filthy garments that find their way to the school room loaded with diseased germs. The clothes of the poorest child may be worn and patched, but they can and must be clean.

It has been seen that the carrying out of local health matters is largely a failure. The local or district management of schools is but little better, and the history of the Connecticut schools shows that one hundred years ago when the towns relinquished their control to the districts it was a grave mistake. With this experience the matter of the health of the school cannot be left either to the local board of health or to the district, for in such circumscribed localities the requisite talent and fitness is scarcely to be found and unless the law defined the duties of each, as it does in New Jersey, there would be constant clashing between them. This work must be entrusted to skilled men, independent of local prejudices and influences, and to men competent in school matters and of a character to entitle them to consideration. It could be entrusted to either the State Board of Education or of Health, as is the case in New York and New Jersey. But our State Board having such a bureau in charge, would require the services of hygienic experts. The State Board of Health could not depend upon the health boards of towns. Massachusetts has a special bureau called the District Police, which seems to give satisfaction.

We would not be understood as disparaging the work or the influence of our present State Board of Education. They are working along the educational lines and doing all that the law

permits them to do. They have a secretary who devotes his time to ascertaining the condition of the schools, enforcing the truant laws, superintending the State Normal Schools, attending conventions, and making annual reports. All this is promotive of great good, but as now constituted, without any sanitary or medical men on the board, it would be inadequate in the very nature of things to superintend the health department of the schools.

INSTRUCTION.

No sanitary laws or system of inspection can be enacted that stands in any degree above the public sentiment of the State. To elevate public opinion is a part of the work to be done by the friends of our schools. Science and sanitary measures must be better understood in the community. They should form a part of the school curriculum. The graduates of our normal schools should be fully taught on the whole subject. They should know a good and a bad school house at sight, and be able to give a critical opinion, to measure the pupil in his organization, his growth, development, temperament and capacity.

Hygiene has of late been introduced as an optional study in the schools. An outline text book or syllabus has been adopted. This is inadequate. A full text book, well illustrated, is needed to insure success. Something might be done with the advanced scholars in selective reading from the current health literature. Whatever knowledge is gained in these matters in the school will be known and discussed at home. Teachers and schools need for a time special instructors to look after this branch of study in towns and larger districts until the subject is more fully introduced.

I have, gentlemen, for the purpose of illustration, given some facts concerning the sanitary condition of our schools; the amount of sickness or physical impairment which an inspection here and there reveals; the phenomenal absence of all sanitary legislation and the great need that exists for skilful and thorough sanitary inspection and supervision.

I could not have made these suggestions to any class of men more ready to appreciate the conditions indicated. It is to be presumed that some of you are officially connected with the schools, but if not, the observations made in your professional lifetime will have disclosed to you more facts than can be related in one brief hour.

It has been said that the Connecticut school has relatively declined. It may be that in the great success, in the glorious tradition of the early schools of the State, we have relied too much upon our inherited advantages, or been too conservative in the adoption of the new methods

of study and management, successful in other States. But our discussion confines us to the lines of health. We presume that in the first schools planted here in the wilderness, though they were under the supervision of such illustrious men as Davenport, Mason, Hopkins, Hooker and Eaton, some of whom had studied the free schools in their exile home in Holland, the matter of school sanitation had never been discussed. Neither did the pilgrims on board the Mayflower discuss the question of putting a steam engine into that little ship. Sanitation is a word of this generation, and already is not fully expressive of the most advanced ideas in this direction. The hygienic watchword to-day in Europe, more than in this country, is a sepsis. It is this that is cleaning the streets of the continent. It is reducing the death rate of cities, and bids defiance to plague and pestilence, and our mission as physicians in this great work is not ended until we see this great principle, not only pervading and permeating our schools, but made authoritatively and permanently effectual. When this is done a long step forward has been taken in regaining the reputation and the glory of the Connecticut school.

ORIGINAL ARTICLES.

RESTORATION OF THE PELVIC STRUCTURES AFTER INJURY.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 5-8, 1891.

BY HENRY O. MARCY, M.D.,
OF BOSTON, MASS.

1. *The Cervical Lesions of the Uterus.*—Little is required to add to the completeness of our knowledge to the present date, upon the surgical treatment of lacerations of the cervix uteri. Thanks to the labors of our distinguished countrymen, the late Dr. Sims and his early associate, Dr. Emmet, of New York, the limitations and advisability of the surgical repair of the cervical tissues of the uterus are generally well understood and accepted by the profession at large, as taught in the great surgical centres of the world. The restoration of the cervical tissues after the proper refreshment is greatly facilitated by the use of the Hagerdon needle, which pierces accurately and with comparative ease the thick, firm cervical tissue. The interrupted silver wire suture, so long used by the followers of these great masters, has been most advantageously supplanted by the continuous animal suture, since this at least equally well holds the restored parts *in situ* and demands from the surgeon no attention subsequent to the completion of the operation. This is, in every way, a great gain by allowing the

parts to remain continuously at rest, saving the patient the anxiety and dread of suffering, consequent upon removal, and the surgeon oftentimes a delicate, troublesome manipulative operation in hunting after and removing the loop of wire. More important than all, however, it is a great gain in that the surgeon may at once proceed to the performance of other operations, if, as is generally the case, such are deemed necessary.

I suppose it need scarcely be added that the manipulative procedures, at least in the present state of our knowledge, are decidedly safer when performed in the most careful aseptic way, including irrigation with mercuric solutions. A vaginal tampon impregnated with iodoform completes the dressing.

2. *Operations on the Vaginal Roof.*—The first in importance, although not in frequency, of the lesions of the superior structures of the vagina, is vesico-vaginal fistula. Here, as elsewhere, we pause for a moment to consider the monumental labors of our great founder of gynecology. Without appreciating the first great cause of failure of sutures, as then applied, as due to septic infection, Dr. Sims accepted the metallic suture as a great gain over all material hitherto used, from the fact that it remained in the wound as an "unirritating" material. He demonstrated the better methods of repair, emphasized the primal importance of introducing the suture, so as not to include the mucous membrane, and worked out with painstaking care the methods of complete closure of the wound, and retention at rest of the coapted surfaces. His dexterity, skill and fertility of resources, are the admiration of all. In this operation, however, for some years, I have advocated the use of the continuous tendon suture, which I think preferable to wire for the reasons advanced in the consideration of its use in the repair of cervical lesions. The secret of success in the use of the tendon suture, is the same that pertains to Dr. Sim's operation, greatly aided, however, by our knowledge and appreciation of aseptic conditions, without which failure will ensue, no matter how carefully we obtain what Dr. Sims considered as the fundamental factors, retention at rest of the carefully approximated refreshed surfaces by the means of the "non-irritating metallic suture."

3. *Cystocele.*—The condition is not exceptional, where, for reasons already referred to, the anterior wall of the vagina has become so deformed that it produces a protruding pouch which contains the base of the bladder descending on a plane below that of the orifice of the meatus. Fortunately for the surgeon, the conditions here are quite unlike those which pertain to the posterior segment of the vagina in rectocele. Owing to the more or less constant effort in micturition, and other causes, the vagina, although weakened as a means of support, has become greatly thick-

ened anteriorly and its vascularization increased. The surgeon having determined upon a reformation of the vaginal tract, after having duly cleansed the parts, marks out the portion which he intends to resect. The size and shape of the piece to be removed will, of course, depend upon the conditions present. It may be a simple ellipse, or a portion upon either side near the cervix in addition may be deemed wise to be removed, possibly including the entire cervix, in certain cases of hypertrophy of the organ. Few plastic operations are attempted with more dread by the inexperienced, owing to the fear of wounding the bladder. It was on account of this that most of the early operations, where the attempt was made to pare off with the scissors the mucous membrane only, and intrafold the vaginal muscle, resulted in failure. The method of operation is really simple. At the commencement of the prolapse, above the urethra, a division is made entirely through the vaginal muscle to which the bladder is loosely connected. With a little care, by means of scissors, a desired resection is made, the loose connective attachment to the bladder making the separation easy. When in doubt, it is well to minimize the piece removed and adjust the edges the better to determine the effect, since it is easy to pare away the redundant tissue afterward, if necessary. We cannot help thinking that the following method of suturing is to be recommended over that generally in use. By means of a fully curved Hagerdon needle, introduce aseptically the animal suture, preferably tendon, in the following manner. It is presumed that the operation thus far has been done in the lithotomy position, the parts having been fully exposed, by the use of the retractor speculæ. The continuous stream of the irrigator washing the parts clean, the bladder wall is elevated by some flat instrument, and the suture is introduced, commencing at the cervical portion of the wound, from a quarter to a third of an inch away from the cut surface of the vagina, from side to side, in a continuous running or lacing stitch, thus completely approximating and supporting the divided edges of the vaginal wall by a line of buried sutures; the last stitch is carried entirely through the vaginal wall, at some distance from the meatus in front, away from the cut surface. A second line of sutures is carried from within outward, through the deeper portion of the vaginal wall, parallel to the first line, closely uniting the divided edges, and yet none of the stitches penetrating through the mucous membrane, thus making a second line of buried sutures. Finally the suture is made to emerge very closely to the exit of the first, where the two are joined by a knot and the ends cut short. The vaginal wall is now very carefully dried, dusted with iodoform, painted over with iodoform colloidum, into which a very few fibres of cotton are

introduced, and a dry tampon of iodoform wool is applied within the vagina. This method of uniting the refreshed parts in vesico-vaginal fistula is sometimes advised, where the wound is sufficiently large to allow of the union of the tissues by burying the sutures in their different layers. In both cases, a retaining catheter should allow the free escape of the urine in order that the approximated tissues may remain at rest. A rare form of injury to the parturient tract has been pointed out by Dr. Emmet, of New York, of which I have seen but a single complete example, although, I believe in a minor degree, it not very unfrequently is associated with lesions of the perineum. It consists of a more or less complete tearing away of the vagina from the connective tissue attachments to the surrounding organs, by its becoming folded over, or fixed, so to speak, to the advancing head in parturition. It is important to bear in mind the possibility of this lesion, of which the following case is an exceptional example. Mrs. M., aged 28, otherwise healthy, was sent to my hospital in 1889, under the supposition that she was developing cancer of the vagina. Her history, briefly, was that about 18 months previously, after a long and tedious labor, the first pregnancy, she was delivered of a still born child; convalescence was tedious and imperfect, with much local pain and discomfort continuing to the present. There was a moderate laceration of the perineum, but just within the vulva there was a firm, hard, inelastic ring, which barely admitted the tip of the index finger. Upon dissection it proved to be cicatricial, consisting of a fold of the vaginal muscle, which extended upon either side nearly to the meatus. Restoration of the parts was effected by dissecting, entirely free from its attachments, a little more than three quarters of the vagina quite deeply in its junction to the vulva. The perineal structures were now restored and the vaginal tissues normally rejoined to the vulvar outlet. A rapid convalescence followed with entire relief to the patient and complete restoration of the parts.

4. *Repair of Lacerations of Perineum.*—When incomplete the floor of the pelvis presents a great variety of changes, dependent upon the degree to which its structures have been weakened. When the sphincter fibres remain uninjured, the transversi having been separated, and by their perverted action the levator loop is drawn apart, a more or less pronounced rectocele is usually present. Obviously the chief factor in importance is to restore the relation of the groupings of the sundered muscles which go to make up the pelvic floor. A careful examination of the anatomical relation of these structures will make apparent that the injury sustained by the parts is *posterior* to the vagina, and hence, whatever operative measures we would undertake for their restoration, should include the parts in-

volved. Upon reflection, it is clear to all that this is not the vagina, and yet, singularly, nearly all surgeons content themselves by operating upon the vagina after denuding it of its *mucous surface* only. It is true the vagina is deformed, oftentimes stretched out to a thin muscular coat, the rugous surface of its mucous membrane entirely wanting, and yet nearly every operator classed as an author, has dwelt at great length upon the importance of denuding its mucous surface only with the greatest care, and then intra-folding its muscular wall with stitches taken in every variety of manner, and combination of lines, confusing in detail and grading into each other in kaleidoscopic pattern. It is owing to this, in by far the larger measure, that such confusing and uncertain ideas pertain to the profession generally, which makes the repair of the perineum, as usually practiced, one of the most unsatisfactory of operations in surgery. If it be true that the *structures* that go to make up the pelvic floor, and not the vagina, are the ones at fault, then it is equally clear that these are the tissues which merit and should receive our attention. It is not for a moment to be doubted, that most operators have, in a measure, included these structures in their operations upon the denuded vaginal muscle, but at the best this is accidental, faulty, and liable to failure, as we have seen in a similar operation when undertaken for cystocele. I cannot doubt that the true rationale of operative procedures and consequent satisfactory result should be based upon making the dissection *behind* the vaginal muscle and not *upon it*. The procedure is simple and easy.

In incomplete ruptures, with more or less prolapse, the transversus perinei muscle can no longer be felt as a band in front of the rectum, and the levator has lost its tonicity. The restoration of these with the various attachments of the sundered groups is the object sought. The patient is placed in a good light in the lithotomy position upon the table. An inflated rubber irrigating pan with a large efferent tube is placed under the hips. This is a great convenience for purposes of cleanliness. These were first made for me more than ten years ago by the Davidson Rubber Co. Somewhat recently, with slight modification, they have been introduced to the profession as the Kelly pad. The irrigation with a 1-2,000 mercurii bichloride solution is under the direction of an assistant and the entire operation is conducted with aseptic care. After the sphincter has been stretched and the lower bowel cleanly washed, introduce two fingers of the left hand into the rectum, which are not withdrawn until the operation is completed. The posterior third of the vagina is separated with knife or scissors from its vulvar attachments. The recto-vaginal space is easily found and the dissection is carried as far up as the crest of the rectocele

and into the lateral sulci, as far as is deemed sufficient. Their lateral sulci are formed by the retraction of the ends of the transversus perinei muscles, and it is important to dissect well beneath them and free their divided ends, for the reunion of these important structures is dependent upon the ability of the operator to seize upon and firmly hold them in the grasp of his sutures, thus rejoining them upon the median line. Dr. Emmet has very wisely pointed out the importance of taking up the "slack" of these vaginal tissues by his Y lines of suturing, but to my mind has failed to emphasize the pathological conditions and the causes which have produced them.

The separated flap is lifted and held by an assistant, then I introduce a large curved needle, with the eye near the point, threaded with tendon, from right to left, deeply from side to side, beginning at the very base of the dissection, guiding the needle by the finger in the rectum, so as not to puncture it. The suture is unthreaded, the opposite end introduced into the eye and the needle withdrawn. The suturing is continued in this way until the required number of stitches are taken. In rectocele with prolapse and large, deep sulci, the buried sutures are more deeply taken laterally and internally from side to side, in order to join the separated fibres of the levator loop with the retracted, transverse perineal muscle. Usually four or five of the double sutures are required; they are secured by a knot and the ends cut short. The remaining tissues are coapted by a light running suture taken from side to side until all the structures are joined. It is frequently wise to remove a small portion of the redundant, deformed, vaginal tissue, and the coaptation is completed, every stitch being taken so that the suture is not in sight, all remaining completely buried. The parts are carefully dried, dusted with iodoform and covered with a very thin layer of iodoform collodion strengthened with a few fibres of cotton. When the dissection has been properly made, the tissues thus coapted form a firm, full deep perineum. The finger introduced into the vagina recognizes at once the tense reconstructed pelvic floor. With proper dexterity the vulvar organs are reformed to the condition of those of the woman who has never borne children, and when the reunion is primal, which should follow the operation if done aseptically, the convalescence is rapid, without pain or oedema of the parts. It is well to cause defecation not later than the third day; micturition in the knee-chest position may be voluntary, but great care should be exercised to prevent the wetting of the restored tissues with urine. No especial restraint of body is required; a semi-reclining position may be assumed within a few days and the patient allowed to sit up for short periods of time

after the first week. Beyond the careful attention to retain the parts aseptic no subsequent dressing is needed. This, in my hands, has been best effected by keeping the parts dry, by the occasional change of the vaginal dressing, and frequent dusting with the iodoform blower. After some months it is often difficult to trace the line of reunion even under careful examination. I have somewhat recently had the opportunity of examining a patient, where I restored the perineum more than nineteen years since with perfect result, and during the subsequent years of my surgical experience, after a great variety of modification in detail, I have found the above method, all too briefly described, eminently satisfactory. My experience comprises several hundred cases thus operated upon, and it is the very decided exception that failure in any degree results. If for any reason failure ensues, the tissues are in better condition for subsequent operation than by any of the surgical measures usually recommended, since little or no tissue has been removed, all having been utilized in the restoration of the parts.

Operative measures advised when the rupture is complete do not differ materially in principle from those advocated in incomplete rupture. Here, for apparent reason, rectocele is absent, and the hæmorrhoidal venous plexus does not undergo deformation. The edges of the laceration are slightly refreshed, and the vagina from each side of the rent is dissected away as far as may be deemed necessary; usually, as already recommended, to include about the posterior third. The dissection is continued posteriorly on each side of the sphincter ani, in order to be able to reach the retracted ends of the torn sphincter muscle. The lower border of the rectum is reformed by a line of continuous tendon suturing, commencing a little above the rent, in the line of the dissection which has been made between the vagina and the rectum. The stitches are taken from side to side, laterally, within the margin of the refreshed tissue, and the suturing is continued quite to the reformed anal outlet, the end of the suture being left unsecured until a later stage of the operation. It will be noted that this running, or lacing suture, when drawn upon, is entirely buried within the refreshed tissue, while it everts the coapted mucous membrane of the bowel toward the rectal side. A similar line of suturing coapts and restores the vagina. The uncut end of the suture serves conveniently the purpose of lifting upward the vagina by the assistant during the process of coapting the several structures, which is done precisely as recommended in the reconstruction of the parts in cases of incomplete rupture. The double suture is applied deeply on either side of the sphincter, in order to coapt the retracted ends of this muscle. In the failure to do this, a weak sphincter will frequently be the

result, even if complete success has attended the restoration of the other structures. Preliminary to the operation, it is important to have the lower bowel well emptied, thoroughly cleansed by injection of sublimate solution, and a considerable ball of iodoform wool, with string attached for subsequent withdrawal, should be introduced high up into the rectum. The bowel is better moved by the fourth day, and a rectal tube may be inserted as early as the patient seems disturbed by flatus. By this process of restoration, the so-called pin-hole or recto-vaginal fistula can very rarely occur; in fact, I have never seen it to happen, although so commonly resulting by the methods usually advised. Success of course depends upon doing the operation under aseptic conditions, and retaining the parts devoid of infection during the processes of repair. I have frequently seen this most troublesome affection cured, as completely as when undertaken for the simplest of lesions.

I cannot help thinking that the measures above described are to be earnestly commended as simple, safe and effective; but they must be executed with the most rigid aseptic precautions, without which failure will not only ensue, but the gravest dangers, not alone to the parts involved, but to the life of the patient, may readily follow.

The pathological conditions which pertain to the rectal tissues result, in very large degree, from changes in the vascularization dependent upon the dilation of the hæmorrhoidal veins. These are often deformed to an extent rarely appreciated by the ordinary practitioner, and only to be understood by the surgeon, who makes the vivisection for the purposes of cure. I have elsewhere treated this subject in detail, and refer to it here for the purpose of completing the subject of plastic operations for the restoration of the pelvic structures in women, resultant upon pathological conditions. I am constrained to believe, as I think for abundant reason, that the ligature and cautery, destruction of the tissues by acid, etc., are not alone unsurgical and barbarous, but often fail in the end of securing the desired result, since a portion of the deformed structures, not seldom, remains unchanged, but also that tissues, of importance to preserve, are thereby frequently destroyed. A complete dissection of the deformed hæmorrhoidal plexus, as advocated by Mr. Whitehead, in my judgment, offers abundant reason for adoption, and the only criticism I have to make upon his method, is the closure of the wound with interrupted silk sutures. This method has been severely criticised and in great measure failed of general adoption, because of the fear of hæmorrhage, which during the indefinite past has been emphasized as liable to pertain to any of the methods applicable to the cure of hæmorrhoids. This is doubtless greatly overestimated by the profession at large. The dilatation of the

hæmorrhoidal plexus is, indeed, sometimes truly enormous, but it will be found, upon dissection, that the vessels quite within the grasp of the sphincter are usually very little changed, and that here their constriction is simple and easy. I have for some years operated in a way to be commended as in large measure bloodless, and assuredly without danger of subsequent hæmorrhage. The procedures are briefly as follows: The sphincter muscle is dilated and the parts put on tension by two fingers in the rectum. Either with a sharp knife or scissors, division is made upon the line of the juncture of the skin and mucous membrane. With a little care, the veins are separated from the loose folds of connective tissue without injury, down to the line of the sphincter muscle. They will be found closely connected with the everted, thickened mucous membrane, a portion of which it is well to remove. Division should be made through it upon the line selected for excision, and a continuous row of double tendon sutures is rapidly made to encircle the base of the hæmorrhoidal plexus. It is then resected with scissors, and a light line of continued running sutures encloses the deeper layer, and when gently drawn upon, taken as advised, from within outward, are themselves buried, leaving no stitches in sight. Carefully dried and dusted with iodoform, the operation is completed by painting the line of closure with a layer of iodoform collodium. It is usually better that three or four days elapse before defecation ensues, after which there is little suffering. With the paralyzed muscle at rest, the conditions of the parts remaining aseptic, pain and œdema are almost entirely wanting, and the contrast between the suffering, and too often defective result, pertaining to the measures usually in vogue, is so marked, that I cannot help thinking that he who gives this operation a careful trial, will abandon all others for the cure of hæmorrhoids.

To resume, it will be seen that the above group of operations are based upon a tripod of simple factors:

First—Clean dissection in aseptic tissues, aseptically maintained.

Secondly—The restoration of the parts to their normal relations, by means of animal sutures, preferably tendon, aseptically buried, and the wounds protected from external contamination and infection, by the simplest possible methods of dressing.

Thirdly—Retention at rest.

The tissue, aseptically maintained and held at rest, for a few days only, take on repair without pain or suffering. The collodium seal is less satisfactory upon wounds of the mucous surfaces than upon the skin; however, it is surprising to note the rapid changes inductive to repair which go on in an aseptic wound, and to this end, external protection after a brief space of time is far less

important than was earlier supposed. In the light of great principles, founded upon scientific data, of practical value for the well-being of our race, personal questions sink into insignificance and are deservedly worthy to be forgotten. However, I trust it will not seem presuming, in claiming for myself the merit which I know a generous profession is willing to grant to all scientific measures which are deemed worthy of approval. The use of the buried animal suture seems almost as a corollary in the problem of aseptic wound treatment, especially when we take into account that the great principles upon which its adoption is based were clearly demonstrated by the immortal founder of antiseptic surgery. Mr. Lister traced with pains-taking fidelity the changes which ensue upon the closure of a great vessel by the animal ligature when aseptically applied. Indeed, these changes, when the tissues chanced to be aseptic, had been as clearly pointed out, and the results demonstrated, in the early part of the present century, by American surgeons, whose work is now well nigh forgotten, although deserving of a permanent place in the history of surgery. Dr. Jamison, a distinguished surgeon of Baltimore, published a prize essay in 1827, replete with demonstrations upon the lower animals, in which he follows with rare acumen the changes which ensue in the ligation of vessels in continuity, by the animal ligature. The material employed was, for the most part, narrow strips of deer skin tanned after the methods in use by the American Indians. The skin when finished being soft and pliable, somewhat resembled the chamœis skin of commerce, although a very much tougher and stronger product. Dr. McDowell, the founder of ovariectomy, used such a ligature for tying off the pedicle in his first case of ovariectomy. The celebrated surgeons, Drs. Physick and Dorsey of Philadelphia, Dr. Nathan Smith of New Haven, and others, including Sir Astley Cooper of London, made use of such ligatures cut short and enclosed within the wound, and wrote approvingly of the results. Governed, however, by the theories of irritative conditions, inflammation and vascular changes which occurred in the tissues, all obscured by the want of accurate knowledge of aseptic processes, the practical lesson which these men taught was lost to surgery until a better pathology demonstrated the now well defined lesson of septic and aseptic conditions which pertain to wounds. Directly after having received personal instruction from Mr. Lister in 1870, I operated upon a case of hernia, where the abdominal opening was so very large it became necessary to close it in order to retain its contents; this I did, although with much misgiving, by the use of interrupted sutures of catgut closed within the tissues. The wound was dressed antiseptically and primary union followed, with a permanent resulting cure of the hernia.

The lesson taught bore fruitage in a series of histological studies upon sutures buried in the tissues of different animals, killed at varying periods, after the introduction of the suture. The material used was primarily catgut, and afterward tendon taken from a variety of animals. I demonstrated that, little by little, the suture became infiltrated with new connective tissue cells which, in a very considerable degree, not alone surrounded, but replaced the buried suture. The limit of this paper prevents further detail, except a brief reference to my publications upon the subject.

My first case of operating, already referred to, occurred in February, 1871, and my first publication was in the *Boston Med. and Surg. Journal*, November 16, the same year. I have repeatedly called the attention of the profession to this subject, in various articles published from time to time until the present. So far as I am aware, the priority of my publications upon the various uses of the buried suture has never been questioned in America, but in Germany, I understand, such honor has generally been accorded to Werth, whose first contribution upon the subject was in 1876, five years after my first publication upon the subject. Experience in the hands of many operators has now carefully demonstrated the wide applicability of the buried animal suture, covering the entire field of operative surgery when aseptically applied itself aseptic, in aseptic wounds. In such wounds, when the tissues are evenly coapted, drainage is no longer required, and any material left in the wound for the purpose, is not only superfluous, but positively detrimental and dangerous, since wounds thus closed, no matter how large, including even the major amputations, may be sealed with the germ-proof dressing, and all subsequent attention, beside retention at rest, is unnecessary.

POST-OPERATIVE PERITONITIS.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, Washington, D. C., May 5, 1891.

BY BENJ. T. SHIMWELL, M.D.,

DEMONSTRATOR OF SURGERY MEDICO-CHIRURGICAL COLLEGE,
PHILADELPHIA.

The object of this paper is to bring forward, for discussion, certain symptoms that follow after operations in the abdomen.

The value of proper drainage, in this class of work, is fully appreciated. Some operators being so enthusiastic as to enforce its use in almost every case. This enthusiasm deserves more commendation than condemnation.

The necessity that requires such means, is a result of the condition on which the title of this paper is based.

To properly understand the idea intended, there must be an appreciation of the distinctive differ-

ence between the two conditions, sapræmia and septicæmia. It is a state of sapræmia due to the absorption of a chemical product into the system.

The tendency of an injury to any closed serous cavity, is to result in an inflammation which will diffuse itself over its whole surface, unless there is contact and adhesions formed which limit its extent. It is this peculiarity that accounts for peritonitis following operations.

This is an asthenic inflammation. The difference between this and the sthenic is in the character of the exudation. This is explainable on the theory that there is alteration of the functional activity of the peritoneum, produced by the interference, resulting in the engorgement of the vessels and transudation of the serous contents. It is an inflammation which does not go beyond the first stage and its serous exudation. If it was to pass into the second, then we would have fibrin and cell elements present, forming adhesions constituting what the pathologists call the chronic stage.

The existence of a pure serous exudation is doubted by pathologists generally. They admit it does, but claim it contains fibrin in more or less quantity. If it is present it must be in its primary elements.

The seriousness of this effusion is entirely governed by the quantity: when slight, the peritoneal surface is able to remove it; if greater, then positive means must be used or death will occur.

The presence of this fluid is caused by involvement of the whole peritoneal surface.

The limitation of this condition is governed by the recuperative powers of the individual, and the influence the operation has on the system at large.

It is a congestion, with consequent exudation, due to paresis of the vessels. The development of germs is the secondary involvement, and on this depends the result.

We know that the peritoneal surface is able to take care of pyogenic organisms, providing the condition is such that their absorption may take place. Yet an abnormal state of this membrane or an abrasion may be sufficient to allow of their full development. Experiments have proved that saprophytic bacteria can be absorbed in large quantities, yet, if there is an interference in the functional activity of the peritoneum or the exudation be so increased as to interfere with rapid absorption, then sapræmia will occur. There will not be suppuration in these cases. This is a point in the argument. In this form of peritonitis absorption does take place, more or less rapidly at first, then extension of the condition interferes with the action of the lymphatics, and consequently there is partial stasis. This state being present, the pyogenic organisms existing develop and rapid intoxication results.

Retained blood clot, shreds of tissue, imperfect

coaptation and the exudation from denuded surfaces furnish means for the development of micro-organisms independent of any other condition. The effusion with development of germs, that is incited by the presence of these foreign substances, give rise to a state that is not of the character dealt with by this paper. It is septicæmia, not sapræmia.

To account for the presence of these micro-organisms is not my object. Whether they are introduced from without, excreted from the blood or derived from the intestinal canal, is an open question.

It is not scientific to say, because plasma and adhesions are not present, that this condition is not peritonitis; sufficient to the fact is the existence of this serous exudate.

We cannot overlook the fact of the localized peritonitis created by the interference, which exists in every case operated upon. No one will deny the fact that exudation takes place and that the absorptive power of the peritoneum is brought into play or relief is sought in the drainage tube.

I have had, in my experimental work on the dog, serous exudation occur after operations. The quantity varied in extent. Post-mortems would show the intestines congested and free of plasma. Mesentery always shortened. The point of operation showing plastic exudation, there being either good union or secondary softening of the exudate.

Pus was never present at any place in the abdomen but at the point of operation. It is therefore proof that the exudation was free from fibrin; for if not suppuration would have been more diffused. As fibrin and cell elements are necessary for suppurative change, it can readily be understood why this condition does not exist. If the exudation is thrown out on the serous surfaces there may be sufficient plasticity to maintain their contact, and fibrinous union occur. This is possible if there is modification of the conditions with absorption of the fluid, but if this persists the fibrinous network gives way. The effused leucocytes become fatty, degenerate, and suppuration follows.

How often have post-mortems shown the place of operation covered by adhesions, and yet a serous exudation in the pelvic cavity.

Why two operations will give diametrical results, when done under the same conditions, is difficult to explain.

Why a simple oöphorectomy will end fatally, and another, followed by necrosis of the stump and suppuration, terminate with discharge of ligature and recovery, is more easily explained. In one, necrosis has not occurred and inflammation extends according to the law of serous cavities. The other has necrosed, adhesions form, limitation of inflammation takes place and suppuration occurs.

The classical symptoms as recognized in peritonitis are absent, or modified, when present, and on these grounds do cases deceive.

A close observation of cases that have come under the writer's care, has convinced him of the existence of certain facts that are more or less constant. One of the most prominent symptoms of so called idiopathic peritonitis is pain.

In post-operative peritonitis this symptom can truly be said not to exist. If present, it is very slight and is generally localized, being due to existing adhesions. It is apt to escape attention unless careful palpation of the abdomen is made.

Tympany exists in an exceedingly mild form. In some cases it is not apparent. This is in part due to contraction of the mesentery which holds the intestines close to the posterior wall. I have seen the liver dulness over two inches above its normal position by distensions of the transverse colon, and yet the abdominal wall was flaccid.

The temperature sheet, in the average case of this kind, shows nothing characteristic. Constancy is not present. Rise and fall making no change in the general condition. A gradual fall from 103° to 99° has neither cleared the cloudy sapræmic brain nor lessened restlessness. The rise again at unsuitable hours has not increased, nor changed the existing condition.

In these cases post-mortem shows nothing resembling the idiopathic form. Here, effusion of bloody serum is present, in variable quantities, situated in the pelvis, located there by gravity. Adhesions are not present, except localized by Nature's attempt to limit. There is not the diffused matted or attached intestines.

There is one sign in the diagnosis that I think is conclusive in forming an opinion. I have found it present in all forms of peritonitis. The so-called idiopathic, tuberculous and post-operative. It is the absence of Douglas' cul-de-sac as felt through the rectum. Every one who has examined many rectums knows, that when the finger is introduced to the anterior, that after passing beyond the internal sphincter there is felt a mass that has the sensation as if the rectal walls had prolapsed; this is always pushed aside and the continuation of the canal is followed. This mass is made by Douglas' cul-de-sac, which pushes the rectal wall downwards. If the rectum is examined, in a case of peritonitis, this mass will not be present; instead, the finger will turn about in space and have to be introduced farther into the bowel; in some cases pushing the anal surface upwards to reach the roof made by the floor of the sac. This is most marked in the male. I have been unable to feel the floor of the sac even when the abdomen was full of fluid and the belly walls excessively distended. This is due to the contraction of the mesentery, which draws up the rectum, obliterating in whole or part, the recto-uterine or recto-vesical space.

A RERORT OF THREE SUPRA-VAGINAL HYSTERECTOMIES AND SIMILAR CASES TREATED BY ELEC- TROLYSIS.

*Read in the Section of Obstetrics and Diseases of Women, at the
Forty-second Annual Meeting of the American Medical Association,
held at Washington, D. C., May, 1891.*

BY THOMAS OPIE, M. D.,
OF BALTIMORE, MD.

Mrs. L., age 48, was married at 28. Menstruation began at 16. This function continued regularly, painlessly, normally, throughout her unmarried life and during her married life until six months ago, when she began to menstruate on alternate months. She never conceived during her 22 years of married life, though her husband was a healthy man and both enjoyed to the fullest extent the conditions of sexual union.

Five years ago, she first noticed an enlargement of the abdomen; she observed that she was "short-waisted." Pressure symptoms manifested themselves in disturbances of the digestive system two years ago and were her only annoyance, save the mortification growing out of her abdominal development.

There has been no vesical nor renal disturbance, at least so far as the patient remembers, because, like the uterus of advanced pregnancy, it has for five or six years been an occupant of the abdominal cavity.

The lady on her first visit to my office stated that she had been examined and an opinion obtained that she had an ovarian cystoma, but her friends were unalterably opposed to operative procedure.

The conditions of fluid contents were satisfactorily made out, but my indecision as to its exact character was manifested by my double equipment for the operation either as an ovarionomy or a hysterectomy.

After thorough aseptic, indeed absolute antiseptic preparation of the patient, operator and assistants, an incision was made from the ensiform cartilage to the symphysis pubis, a distance of 14 inches. The tumor was brought forward through the incision and Baker-Brown's clamp supplemented by two Koeberle scissors clamps were made to constrict the pedicle, which was the uterine neck. Despite this precaution hæmorrhage ensued, but was promptly arrested by seizing the vessels with artery forceps, ligaturing them and tying the pedicle in three sections, the middle one by the saddler's stitch.

The tumor weighed over 20 pounds, its antero-posterior circumference measured $23\frac{1}{2}$ inches, and its transverse circumference $22\frac{3}{4}$ inches. Its shape, lying upon the table, might be simulated by a bladder in the same position, three-fourths distended by water. The diameter from the pedicle to the fundus was 13 inches, the transverse

diameter 12 inches and the vertical diameter $9\frac{1}{2}$ inches. The intra-vaginal portion of the cervix was not enlarged, the body of the fundus apparently monopolized all the pathological elements.

The general outline of the tumor was the smooth hypertrophied and symmetrical appearance of the uterus of advanced pregnancy, in strong contrast with the irregular and nodular characteristics of the typical fibroid. The ovaries are both intact in the specimen and are located near the section of the stump, equi-distant from it and exactly opposite each other. There were absolutely no adhesive bands or other evidences of there having been at any time inflammatory trouble.

The microscope showed a large preponderance of fibrous tissue and that the numerous dilated lymph spaces were filled with fibrin. The fluid contents of the tumor coagulated immediately after its removal.

In pregnancy the development of the uterus out of the pelvis into the abdominal cavity, so as to make the woman "short-waisted," would take at least four and a half months. In a measure there is a parallelism between the normal and this so-called abnormal growth, since both are nutritive in their character, the one in the main muscular, and rapid, the other fibrous and slow. It is set forth in the history of this case that since it began its abdominal development, five years have elapsed and it had now attained the size of the uterus at full term. In view of the law of uterine development, we might assume that this fibroma had an intra-pelvic existence of at least five years, and therefore the whole period of growth was at least ten years.

The early stage of the tumor was even more mysterious and inscrutable, than the early stages of pregnancy. The patient informs us that her first and only intimation of her condition was, that she was getting "short-waisted."

A pertinent and practical question is, when did this cystic degeneration begin and what is its significance as bearing on the health and longevity of the patient?

The temperature has never risen since the day of operation above 99° , nor the pulse over 78. The Koeberle clamps, were removed on the second day, and the Baker-Brown clamp on the tenth day. The silk-worm-gut sutures with which the abdomen was closed, were removed on the twelfth day. The whole extent of the wound has been sealed by primary union, except the lower end of the incision corresponding with the stump of the pedicle which granulated healthily, the abdominal peritoneum being securely united to the peritoneum of the pedicle. I may say, at the time of this writing, the twelfth day, that with a sensible and manageable patient like the one in question, there is but one possible danger ahead, and of that we stand forewarned, viz.: ventral hernia.

Two years ago I met with a similar case of fibro-cystic myoma and operated at a private house with the same fortunate results as in the case just described. The lady recovered without a single untoward symptom and is now plying an active and successful mercantile business.

My third case of hysterectomy for a fibro-cystic myoma was performed 18 months since at a private residence. This patient died on the 6th day. While I cannot state positively the cause of death, since a post-mortem was refused, my belief is, she died from sepsis.

The length of the incisions in the last two cases referred to was about 12 inches and weight of each over 15 lbs.

The mode of operating in these cases is in dispute, though Keith, the most successful of all hysterectomists, advocates the extra-peritoneal plan, as do Pean, Hegar and Bantock, while Schroeder, Billroth and Koeberle, the author of the "serre nœud," practice the intra-peritoneal method.

It is not likely that any one will contend that ergot, administered by mouth or hypodermically, would in any wise curtail growths like the specimen I have described. The removal of the appendices would, if it was practicable in such huge growths, have but little if any influence. I have for two years past used electricity hopefully and for some time enthusiastically, in fibroids of all kinds.

The intra-uterine electrode, as well as the method of stabbing the tumor with the sharp platinum electrode, has been tried frequently and while the applications seemed to improve the general health of some cases, stopped hæmorrhages and greatly relieved dysmenorrhœal pain, I cannot claim to have dissolved any single fibroid or made even an arrest of growth of a cystic fibro-myoma. I caused an abdominal peritonitis by a puncture of a large fibroid through the abdominal wall, and have seen one case, where sepsis was caused by a physician, in the use of an intra-uterine electrode.

I have, at this time, under treatment two large fibro-myomata both of which have developed above the umbilicus; one has had about 80, the other 50 intra-uterine applications, one case has ceased to have hæmorrhages, both have improved in general health.

I recall the case of a fibroid, which I detected when as small as a pea, located on the anterior lip of the cervix. It was not only favorably located for ready application of the current, but for the easy recognition of changes in its size. In the last 18 months I have made 25 electrolytic applications to it. It has trebled its size despite my currents.

I may not be as expert with my batteries as others who are claiming so much for electricity in the solution of fibroids, but I insist that I have,

after over two years of persistent effort with a considerable amount of material, some justification for having lost my enthusiasm and even in being discouraged as to this so-called conservative plan of dealing with fibroid tumors, pyosalpinx, cystic ovaries and the like disorders, which in many cases march straight on to death, or what is worse, to chronic, hopeless invalidism.

The treatment of fibro-cystic myomata by electricity, is well nigh obsolete. Cases have been recorded where abscesses have resulted and ended fatally. Whether aspiration and drainage of such tumors in conjunction with electro-puncture will remove the dangers, is not yet proven.

As soon as fluctuation is determined in a fibroid, extirpation should be resorted to.

The rules of differentiation, the attendant dangers and the treatment of fibro-cystic myomata are the same as ovarian cystoma. Indeed, the operation of gastrotomy for tumors involving the uterus has been evolved out of the work of the ovariologist, in the last quarter of a century.

Whenever an ovariectomy is performed the equipment of an operator should embrace the additional instruments required in a hysterectomy.

A CASE IN OBSTETRICS, FOLLOWED FOR MONTHS BY A DAILY DISCHARGE OF OVER TWO QUARTS OF A WATERY FLUID THROUGH THE CERVICAL CANAL.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY JOHN HAMMOND BRADSHAW, M.D.,
OF ORANGE, N. J.

On December 9th, 1890, a colored woman, aged 34, was confined at the close of her seventh pregnancy. She had borne three girls alive and easily, and three boys, two dead, and all with great difficulty. Finding a face presentation, apodalic version was performed, but not before two ineffectual attempts with the forceps had been made. The child was a male, weighing 12½ pounds, with a large ossified head. It was dead. The woman had been in labor two hours. After the birth of the placenta, there was an unusual amount of hæmorrhage, and the patient went into a condition bordering upon collapse. The extremities were bandaged and ligated, and whisky was administered with digitalis by hypodermic injection. Two quarts of a hot corrosive sublimate solution 1-3000 were thrown into the uterus, the hand carrying the nozzle of the syringe to the very fundus. There were no new lacerations to be discovered, and the patient made a fair convalescence without much pain and with but little elevation of temperature. Three weeks

after delivery the patient was seen because of a flow of water that came from the vagina, wetting the bed and everything upon which she was placed. Fearing the existence of a vesico-vaginal fistula, the patient was carefully examined with a speculum. The vaginal wall was intact and a watery discharge could be distinctly observed, coming through the cervix, which was badly lacerated. The probe passed only into the uterus. At the suggestion of Dr. William Pierson, a pint of a colored solution was injected into the bladder. But as none came through the cervix, the patient, after a few minutes, passed the entire quantity again *per uretham*. As the patient's life was made miserable by the constant wetting, one of Jay's urine bags was inserted into the vagina to catch the fluid that came so copiously through the cervical canal. During the first twenty-four hours this caught just eighty ounces of a clear, colorless fluid, of no smell, a slight cloudy sediment on standing, sp. gr. 1001, alkaline reaction and slightly albuminous. Microscopically, there were found pus cells, granular detritus, a few large, epithelial cells and fibrin. The patient had voided in this time 18 ounces of urine of a rich amber yellow, sp. gr. 1018, acid in reaction, and with normal appearance under the microscope.

An examination of the patient revealed nothing in the pelvis or abdomen out of the way. The patient had never been seen by the writer before her accouchement; she had herself never observed or felt any swelling or abdominal tumor; she had never had a large abdomen.

During December, January and February the patient passed daily through the cervical canal, actually, over two quarts of this colorless fluid. Her appetite and general health was fairly good; she gained in weight and flesh; there was never any distention of the abdomen. But the patient was an invalid—she could do no work, and lay on her bed most of the time. Consultations were held, and Drs. Ill, Pierson, Harvey, Graves and Stickler saw and examined the patient.

During several of the examinations a probe was passed apparently through the fundus of the uterus into the abdominal cavity. It entered easily and without force, almost to a limitless extent (at least its entire length and that of its handle), while its point could be felt close under its abdominal wall above the umbilicus.

For three months she passed about two quarts of this colorless fluid through the uterus. At the end of this time the patient was given $\frac{1}{2}$ grain codeia every three hours, with the hope that it might diminish the flow. This it speedily did, and in two weeks time the patient removed her Jay bag, as she passed but a few drops of the fluid per day. The codeia made her very drowsy at first and some constipated, but not so much so but that an enema would give relief. The codeia

was then stopped, whereat the discharge began again, but only to the extent of four to sixteen ounces a day. At this time Dr. Howard A. Kelly saw the patient in consultation.

At the present time, just six months from her confinement, the patient, provided she keeps still, passes little or no fluid. If she walks about she voids from two ounces to a pint a day. She still takes the codeia, but at intervals of several days, and then only if she has pain or if the discharge of fluid is profuse.

The writer has purposely refrained until now from giving any definite diagnosis that will explain the source of the discharge. There has been a difference of opinion. After watching and studying the case for a long time I affirm that this fluid comes from the peritoneal cavity and is generated by the peritoneum. By the majority of those that have seen the woman it is held that an opening exists in the uterine wall, making a free communication with the peritoneal cavity. It is hoped that if any are present who have seen and examined the woman that they, as well as others, will express their views.

The patient remains an invalid. Can an operation or any other kind of treatment relieve her of her affliction?

THE USE OF VAGINAL TAMPONS.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 5, 1891.

WILLIAM A. B. SELLMAN, M. D.,
OF BALTIMORE, MD.

I am extremely doubtful whether I have selected a proper title for the paper which I have the honor of presenting to this section.

The placing of cotton or materials of similar nature in the vagina is termed tamponade, where a small amount is placed in the canal for purposes other than hæmostatic. Tampon signifies the complete packing of the vagina to stop or avoid uterine hæmorrhage.

I use the word tampon in its broadest sense to denote placing of cotton, jute, etc., in small or large quantities, either for hæmostatic purposes or as a means of placing drugs against the cervix uteri, or as a preventive to the escape of liquids we have applied within the uterus to prevent them passing down and irritating the external genitals. Most gynecologists, when they treat their patients in the office, apply a pledget of cotton against the cervix to prevent the irritating agents employed in the treatment of the case from escaping and excoriating the external genitals during the journey to their homes.

I do not propose to add to the present knowledge in regard to the beneficial action exerted by the applications made on these tampons, or enlarge upon the good results obtained by their

use as a means of supporting displaced organs. Neither do I intend to tell you how to make them, or introduce or remove vaginal tampons; you are thoroughly experienced in all these matters. I rather intend to convey in this paper my impressions of the dangers attending the use of tampons, and I will also endeavor to prove that on many occasions when we think that we have applied them in a scientific manner, that it has been improperly done, and carried out in a manner that will do much harm to our patient, and, perhaps, develop injuries that may require months of treatment to overcome.

In the first place I declare that vaginal tampons introduced for hæmostatic purposes are seldom required, and when used are likely to be attended or followed by great injury to our patient. I make this exception, the use of the tampon for the purpose of provoking uterine contractions and softening of the cervix in cases where we desire to bring on premature labor, as for example, cases of placenta prævia. The packing of the vagina is sometimes justifiable in cases of hæmorrhage due to the presence of uterine fibroids.

I do, however, object to the indiscriminate use of tampons to control uterine hæmorrhages. Examine and find out what has caused and is keeping up the hæmorrhage; remove the cause and the flow will cease. Many a woman has had tampons placed in the vagina where the hæmorrhage has been due, either to retained placental shreds, or perhaps to fungosities existing on the uterine walls. The use of the curette will remove the cause and the flow will cease. If you use the tampon in cases of this nature, the collection of blood, etc., will finally distend the cavity of the uterus, and perhaps dilate the opening into the Fallopian tube, frequently expanding this canal, and the fluid passes into the abdominal or peritoneal cavity. In a practice extending over a period of twenty years I have never seen a case where I have found it absolutely necessary to tampon to relieve uterine hæmorrhage. I have invariably sought for the cause and gave local treatment or removed it.

Dr. Mundè says, "Every practitioner who takes, and is liable to meet with, cases of uterine hæmorrhage, from miscarriage, polypi, polypoid endometritis, fibroid uterus, or cancer, should not only possess a Sims' speculum, but know how to use it and how to tampon the vagina so securely that not a drop can escape so long as the tampon is retained."

I take exception to this teaching and think that it is likely to mislead and be productive of great mischief to the general practitioner, and the medical man starting out in his professional career dependent upon the advice and experience of his teachers to guide him in the treatment of this class of cases. He is likely to feel too safe

so long as he perceives no oozing by the side of his packing, and loses sight of what may be taking place internally. Even in hæmorrhage occurring during the progress of cancer of the cervix it is unsafe to tampon. It is far better to apply a hæmostatic agent directly to the bleeding surface by means of applicator or syringe.

The presence of tampons in the vagina interferes with the evacuation of the bladder and with the proper emptying of the rectum.

In cases of profuse hæmorrhage I frequently have it suggested to me to pack the vagina until the patient has recovered from the prostration due to the loss of blood; when she is stronger you can remove the cause. I consider this bad reasoning. If you are called to see a case of profuse hæmorrhage from the nose (epistaxis), due to the presence of a nasal polypus, you certainly would not plug the nostrils, you would remove the growth and thus check the hæmorrhage.

There are cases where the hæmorrhage comes from the walls of the vagina where the application of the tampon is justifiable, for the pressure of the packing controls the loss of blood by compression of the bleeding vessels.

Tampons are responsible for the production of serious inflammatory conditions of the uterine adnexa, peritoneum and cellular tissue.

After an application of iodine, iodide of potash, nitrate of silver, sub-sul. of iron, etc., a tampon is frequently introduced in the vagina to prevent excoriation of the external genitals by the fluid flowing out of the vaginal outlet. Sometimes it is a small pledget or thin layer of absorbent cotton wet with glycerine or medicated with borax, lead, or tannin. At other times a larger piece is introduced, forming a vaginal plug. The result is the same in both instances. The secretion in the cavity of the uterus is increased by the agents employed for the application; the cotton placed against the cervix uteri completely prevents the escape into the vaginal canal; the result is distension of the cavity of the uterus by the fluid exuding from its walls, this is accompanied by pain, a sensation of fullness within the uterus, what we term uterine colic. This distension may continue until the fundus is dilated, the opening into the Fallopian tube allows the uterine secretions to pass into the tubes; at times the fluid may distend the entire tube and the secretions pass into the abdominal cavity, setting up inflammation at this point. Very fortunately for our patient, on many occasions after a moderate amount of distension has taken place, the accumulation forces the tampon to one side and the fluid is discharged by the vagina.

In this way I account for the violent pains following intra-uterine applications, even of a mild character, when we have placed the vaginal tampon for the purpose of cleanliness.

When we remember the effect of applying these agents to the mucous membrane lining the nostrils, the free secretion provoked lasting in many cases for twenty to forty hours, we can appreciate the amount of fluid thrown out from the uterine mucous membrane after applications of similar nature.

There is a class of cases having a profuse discharge from the endometrium, the characteristic glairy, white of egg mucus; some physicians treat these cases by merely placing a pledget of medicated cotton against the cervix uteri. This tampon effectually prevents all discharge from passing out of the uterine canal, the cavity becomes distended, the purulent secretion may pass into the Fallopian tubes, setting up a similar inflammatory condition in their mucous membrane as already exists in the walls of the uterus. The tampon under these conditions is dangerous, is productive of great mischief applied in this manner. Many a woman has had gonorrhoeal inflammation forced from the vagina and lower portion of the uterine canal into the Fallopian tube by having a tampon placed in the vagina. I make it a rule never to apply a tampon in specific vaginitis.

I am extremely doubtful of the propriety of the use of tampons placed against the cervix in cases of epithelioma or cancer of the cervix uteri.

It has been suggested that we use tampons in cases of inflammation of the ovaries and the Fallopian tubes; the idea advanced is that the tampon supports the uterus and prevents the organ from dragging and exerting traction upon the uterine adnexa. The danger of using these tampons is that suppuration may take place whilst the tampon is in position, the purulent secretion will pass into the cavity of the uterus and will be prevented from passing out by the presence of the vaginal tampon, and may be forced back into the peritoneal cavity, lighting up inflammation at that point.

The treatment of inflammatory conditions of the cervix and uterine body by vaginal tampons, as suggested by Dr. Engleman, has not accomplished the good results we expected when the treatment was advised by that illustrious gynecologist. One reason of failure, I think, is this one point that I dwell upon with so much earnestness, that is, the discharges are prevented from flowing out of the cavity of the uterus.

In conclusion, I would advise the application of tampons only under the following conditions:

In office practice, after making an application to the endometrium, if the agent employed is likely to flow down and excoriate the external genitals, I place a very thin pledget of absorbent cotton lightly against the cervix; this will absorb the secretions; I tell my patient to remove it immediately upon her arrival home.

In cases of prolapse of the uterus, where there is no uterine catarrh, using it as a pessary. Also in cases of prolapse of the vaginal walls under similar conditions.

After plastic operations upon the vaginal walls where there is no danger of hæmorrhage taking place above the point where the tampon has been placed.

In cases of hyperplasia with little or scanty secretion from the endometrium, I frequently place a small pledget against the cervix uteri; this may be medicated with glycerine, boro-glyceride, glycerate of lead, etc.

The application of tampons to correct displacements of the ante- or retro-character is very unreliable. It is so difficult to place the pledgets so as to avoid increasing the displacement. Besides, the pressure of the tampon often interferes with the circulation in the pelvis. I have frequently had patients complaining of pain located in the hip or down one leg after the application of a tampon or tampons.

NON-SURGICAL TREATMENT OF CANCEROUS UTERI.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY C. R. REED, M.D.,
OF MIDDLEPORT, O.

It is not the purpose of this paper to condemn the surgical treatment of cancer of the uterus; nor would the writer claim that a majority of the malignant diseases of that organ should be treated by medicine alone, for he admits that cancer anywhere should be treated, when practicable, by local remedies, and that general medication has little or no influence over the disease, and the vaunted specific he would only mention to condemn. The proposition to treat cancer with the curette and local applications would appear absurd after reading the above title of the paper, yet the paradox will seem logical, as we proceed to illustrate our position.

The non-surgical treatment of cancerous uteri is the disuse of the scalpel or knife, as unnecessary, in many cases; while probably a majority of cases, when first seen by the physician, require the total extirpation of the diseased organs, but it is not in the interest of medical science or suffering woman, to treat all cases of uterine cancer, at once, by what is called the radical operation. The writer pursued this course several years, telling the patient and her friends that there was nothing to be done for her but total extirpation of the cervix, at least, and better that the whole organ be removed; and as she would not follow this advice, he obstinately refused to do anything, and telling her and friends to let her die if she wished—which she usually did. He has

since concluded that he made a mistake, that a dangerous surgical operation is not always necessary, and that his declaration and acts were not always in the interests of the patient and humanity, nor the science and art of medicine and surgery. If the suffering woman refuses to submit to the knife, of which most all of us have a dread, and is willing to undergo the more painful, but less dangerous, use of the curette and the canter, she certainly has a right to her choice, and the physician should, frequently, gracefully acquiesce. It may be claimed that this *is* surgical treatment. Call it minor surgery, if you please—she and her friends have a right to choose it, they taking the responsibility of the result. There are many other diseases to which women, and men also, are subject, which would best be treated by surgical operations to which they often will not submit, but they should not be abandoned to fate, if they can be cured or relieved by less objectionable means.

The prejudice against surgical operations is innate in the human race, and cannot be eradicated, and it becomes necessary to devise other means of treatment, which may often, at least, attain the same end. The woman should not be subjected to a dangerous operation if she can be cured or relieved by means less fatal. That the removal of the uterus, by any of the means recently devised, is frequently fatal, no one will deny; that cancerous uteri can be arrested in its progress, and often cured, by local treatment attended with little or no danger to life, is a well established fact. The purpose of this paper being to give the result of my own observations, I will quote but a single paragraph from authorities on the subject. In his late work on Diseases of Women, A. J. C. Skene, of Brooklyn, in speaking of treatment of cancer of the uterus, says: "A thorough curetting, followed by powerful caustics, will frequently arrest the progress of the disease."

Mrs. F., aged 60, mother of several healthy children, had passed the menopause ten years since, and had enjoyed good health until early in 1889, when she observed a red flow which at times was profuse, and rapidly destroyed her strength; she also had pelvic pain, and when the hæmorrhage was slight she had a profuse watery discharge, which had the odor characteristic of malignant disease. During 1889 she gradually lost strength and flesh, and spent most of the time in bed. She was attended alternately by two physicians, members of this Association, who had persistently kept from her the true nature of her disease. Not receiving any apparent permanent benefit from the treatment, which was both general and local, and not understanding why she did not get better, she discharged her attending physicians and sought my advice, and I first saw her February 4, 1890. I found her in bed,

unable to sit up but little, emaciated, and the cancerous cachexia well marked, and to relieve her suffering she had contracted the morphine habit, with all its dire results. I should have said her parents were living, each about 90, and she had been a widow some twenty years. On a tactile examination I found a carcinomatous cervix, patulous, and that characteristic feel as when you poke your finger into the nozzle of a shotgun. There were also several nodules which felt like large shot in the posterior part of the vagina. The examination caused hæmorrhage, and on expanding the blades of a bivalve speculum, it was so profuse that I felt relieved when I secured its arrest by applying the pure persulphate of iron.

She was told the nature of her disease, the prognosis of such cases, and was advised to undergo the removal of the diseased organ. This she firmly and pleasantly declined, believing she would not live through the operation, and I did not urge it, as I was of the same opinion. She implored me to do what I could to prolong her life; she wanted to live until her parents passed away, and asked that the attacks of hæmorrhage which she so much dreaded be arrested. I did not think that the body of the uterus or its appendages were involved, and had some hopes that temporary relief might result from active local treatment. She lived in an adjoining State, and I visited her once a week, and each time used the sharp curette, followed by the pure chromic acid. I prepared a swab of absorbent cotton, as large as would pass into the cervical canal after I had rapidly reamed it out with the curette, and on withdrawing the latter, immediately dipped the swab into water, then into the dry chromic acid, and carried it as far as possible into the cervix and cavity, and held it there until the hissing and smoke ceased, then withdrew the swab, packed the cervix with cotton saturated with the pure persulphate, which was directed to be removed by a string attached for that purpose, in three or four days. The hæmorrhage from the use of the curette would be fearful, but immediately stopped on contact of the chromic acid. She was directed to let me know should hæmorrhage occur in the intervals of my visits, and but once did she send for me.

When I left home a year ago to attend the meeting of this Association at Nashville, I arranged with a physician near her to apply the treatment in my absence. This was continued regularly for several months, the hæmorrhage ceasing, the local symptoms disappearing, the general health improving, flesh, strength and color returning, and when I left home in October last for a several weeks' visit in the West, I had no forebodings in regard to her case, and when I saw her in November I found her doing her work, apparently well and happy, with scarcely a trace

of her former disease on examination. I have not seen her for several months, though frequently in sight of her house, and learn that she is apparently well. I commenced the treatment of this case with a mental prognosis that it would end fatally in from four to six months—but during a professional life of nearly forty years I have attended no case that the treatment gave me more satisfaction than this, and I have the still greater pleasure of the assurance that the treatment at no time and in no way imperiled her life.

Will the same treatment be generally successful in similar cases? This can only be determined on trial. Could the treatment be as well carried out during menstrual life? Probably not. Will the apparent cure in this case be permanent? Of this I will not affirm, neither can it be foretold of the cases in which the radical operation of entire removal has been done.

It would not be consistent with the intended limits of this paper to give other cases in detail, and had no other cases come under my observation with a similar result, and no case in the literature on the subject, this alone would be sufficient to induce me to use the same or similar treatment before resorting to the operation of removal of the entire organ and appendages, with the present mortality attending the radical operation.

ON THE USES OF COCAINE IN GYNECOLOGICAL SURGERY.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D.C., May, 1891.

BY WM. H. HUMISTON, M.D.,
OF CLEVELAND, OHIO.

I have had an experience in the use of cocaine in gynecological operations during the past three years that has been eminently satisfactory, and I purpose*in as few words as possible to lay the method and my experience before you.

I will first describe the manner of its use in dilating and curetting. Ten minutes before using the cocaine I give a tablespoonful of whisky or brandy. Place patient in the left lateral position, and with Sim's speculum expose the cervix—steady the uterus with a tenaculum inserted in anterior lip. Then take a hypodermic syringe with a fine needle, filled with a 4 per cent. solution of cocaine, which has two minims of pure phenol in each half-ounce of solution, and inject five minims into the posterior lip—wait two minutes, then secure a firm hold with bullet forceps, which will be painless. Proceed and inject in several portions of the cervical canal an amount equal to about twenty minims. I now commence my dilation, with the graduated hard rubber dilators until the cervix is sufficiently dilated to permit the entrance of the

intra-uterine syringe, when ten minims of a 10 per cent. solution is inserted into the uterine cavity. Continue at once with the dilating of the cervix until you have it completed to the extent desired, and then thoroughly curette the entire uterine cavity. This can be done with a slight degree of pain, and in many cases with none at all. I have not given an anæsthetic, other than just described, in dilating or curetting, during the past three years, and the cases include many primiparæ.

For the operation of trachelorrhaphy you can use cocaine and have absolutely a painless operation. Inject the angle, and the sides that you desire to freshen, or a wedge-shaped piece that must come away, and you can complete it all without the patient making a complaint. You will rarely require to use over one-half drachm of a 4 per cent. solution.

For restoration of the perineum in the majority of cases I adopt the split-flap method, and with one puncture of the hypodermic needle in the median line I anæsthetize the whole field of operation, and use only from thirty to forty minims of a 4 per cent. solution.

The hour for operating is usually 9 o'clock in the morning. The patient omits breakfast, and ten or fifteen minutes before the operation the alcoholic stimulant is given.

I say to the nervous timid patients, who are afraid that without chloroform, or ether, that their suffering will be great, that I will stop at any time that they say that they are suffering pain, and give them chloroform. This secures their confidence, allays their fears, and I have yet to hear the first request for another form of anæsthetic.

With this method we avoid the frequent and prolonged nausea and vomiting that occurs after the administration of chloroform or ether. The patients, with but few exceptions, relish their dinner, and their progress towards recovery is rapid and satisfactory. Had chloroform been given, and been followed with persistent vomiting, that so frequently occurs, the whole success of the operation, especially if it be for the restoration of the perineum, would be in jeopardy.

Quite frequently I find patients who are very sensitive, and very small doses will induce short and sighing respiration, together with peculiar sensations in præcordia, accompanied by great anxiety. Stimulants, promptly administered, control this very quickly and all unfavorable symptoms subside.

Twice I have dilated the urethra for fissure and irritable caruncula with but slight suffering, and a satisfactory result was obtained.

I assisted in one case of Alexander's operation where cocaine was used, but two grains in all, one grain injected on each side at intervals of one-half hour. While this was not painless the pa-

tient complained but very little, and withstood the operation well, with no bad after symptoms.

I have selected the following case as one of interest not only for its multiple operations, but to demonstrate the capabilities of cocaine as a local anæsthetic under a prolonged operation. The operations of trachelorrhaphy, anterior and posterior colporrhaphy and perineorrhaphy, at one sitting with cocaine for an anæsthetic:

Mrs. L., aged 39, married nineteen years, two children, youngest 10 years old, came first to consult me in November, 1888, complained of constant backache, very nervous, forgetful, bearing down sensation, felt "as if everything would fall out," to use patient's own language, leucorrhœa, frequent micturition and headache. Patient presented the appearance of a sufferer, pale, sallow complexion, dark lines under her eyes, and quite a degree of prostration. On vaginal examination I found a partial laceration of perineum, os uteri large, swollen, tender and lacerated, edges everted and granular—thick, tenacious secretion in abundance in cervical canal. Uterus prolapsed, body large, tender. Ovaries swollen and very sensitive. Cavity of uterus measured three and one-half inches. Upon directing the patient to strain down the anterior and posterior walls of the vagina bulged forth separating the labiæ. The vaginal walls were hypertrophied and relaxed. Patient was treated locally at my office every third day for two months. Treatment consisted in removing the secretion from cervical canal. Application of iodine and glycerine—scarification—tampons of glycerine, and boracic acid. To be followed at home with copious injections of hot alkaline water. The swollen congested condition was markedly diminished and patient steadily improved until January 10, when patient entered my private hospital for operation. Curetting was done January 11, and the granular hypertrophied endometrium removed and Monsell's solution of iron thoroughly applied to the uterine cavity. This was all accomplished with but little pain after the method previously described. For the next two weeks patient's temperature varied from $97\frac{3}{4}$ to $98\frac{3}{4}$. Patient was kept quiet in bed and after the first week, tampons of iodine and glycerine were applied daily. January 27, uterine cavity measured three inches. Position of uterus higher, and has felt relief from all symptoms complained of. As there was no appreciable pelvic exudate, or signs of remaining inflammation, I decided to make as many of the operations at one sitting as possible; gave patient one-half ounce of whisky. The cervix being lacerated bi-laterally, I made the double operation, first injecting fifteen minims of cocaine in the space I wished to denude. I generally use Skene's hawk-bill scissors to freshen the angles, as it thoroughly removes the tissues from the

whole angle. After preparing my flaps on both sides I united the edges with silver wire sutures, using the spiral coil and shot fastener. Patient complained of but very little pain, and when asked if she could endure more, she replied, "Yes, go ahead." I now exposed the anterior vaginal wall, and injected twenty minims of a 4 per cent. solution, and removed in one body an oval-shaped piece of mucous membrane extending from within three-fourths of an inch of the cervix down for two and one-half inches. This was brought together and united with a deep and superficial continued suture of cat-gut. Some five minutes after this second injection of cocaine the patient complained of dryness of the mouth and fauces, and had some irregular breathing. Another one-half ounce of whisky was given, and soon she was comfortable, and requested to have everything done at once if she kept feeling as well as she was at the present time. The posterior vaginal wall was exposed after Martin's method, and the mucous membrane to be removed was injected in the same manner and amount as the anterior wall; waited five minutes and began removing the portion mapped out; again the patient complained of the dryness of her mouth, and the breathing became short and labored. Whisky was again administered and in a short time the unpleasant sensation subsided. A deep and superficial continued suture of cat-gut was here used, and the edges carefully and evenly brought together down to the line where it was to join the upper angle of the denudation for the restoration of the perineum. At several points in taking the stitches the patient complained of pain, but not sufficient to call for more cocaine. Two drachms of whisky were now administered, and the surface to be denuded for the restoration of the perineum was injected, using again twenty minims of a 4 per cent. solution. After waiting a few minutes I commenced to denude the surface mapped out; no pain complained of, but the former unpleasant symptoms returned, and a little more stimulant was given. The perineum was united with silk-worm gut, using a long-handled needle to put them in. In penetrating the edges near the skin, patient complained of the pain being quite severe, but I did not wish to use any more cocaine, and she endured it with but little complaint or moving. The stitches were tied and the whole time consumed in making the four operation: was one hour and forty-five minutes, and seventy-five minims of a four per cent. solution of cocaine had been used, equal to 3 grains. The patient's knees were bound together, and she was placed in bed on her side. A 2-grain suppository of svapnia was given per rectum. The temperature remained absolutely normal for two days, after which it rose to $99\frac{1}{4}$; the fourth day it was $99\frac{3}{4}$, the highest point

reached, then fell to normal, and remained so during the whole recovery. She was catheterized twice daily for two days, after which voided her urine as usual. The vestibule was well washed with boracic acid solution after each urination. Bowels were moved on the fifth day. The parts were handled as little as could be, and patient kept absolutely quiet. The sutures in perineum were removed the seventh day, and union was perfect. On the 27th day the sutures from the cervix were removed and union everywhere found perfect. No vomiting occurred. This I regard as a severe test for cocaine, and will, I feel, result in removing the great fear arising from the necessity for taking ether or chloroform in order to have these operations performed.

Strict asepsis must be attained in order to have these operations unite and heal readily without inflammation.

LAPARO-HYSTERORRHAPHY—AS A MEANS OF CURE OF CASES OF EXTREME PROLAPSE, OR RETRO DISPLACEMENT OF THE UTERUS.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, at Washington, D. C., May, 1891.

BY W. J. ASDALE, M.D.,
OF PITTSBURGH, PA.

We believe we shall encounter but trifling controversy in asserting that the mechanical treatment of uterine prolapses and displacements has proven to be entirely inadequate to cure, in by far the greater number of cases.

It is safe, too, to declare that the best adapted pessary—while promising palliation only, and not cure—is liable itself to become a nuisance; and not infrequently does beget for the wearer conditions much worse than the former states.

Finally, for a number, including nearly all of the cases of extreme prolapse, and all of the cases of marked retro-displacement with incarceration of the uterus, the use of a pessary or any mechanical support cannot be tolerated: for such, at least—a minority of all, but comprising a large per cent. of the whole—surgical methods must, unavoidably, intervene.

Contraction of the calibre of the vaginal tube, by surgical procedure, by any method whatever, as a means of recovery of the prolapsed womb—no matter how carefully performed, nor how extensive the section, must often fail of permanent good results; this plan, besides, is objectionable for reasons arising out of the social state.

Shortening of the round ligaments, as a method of permanent restoration of the prolapsed or otherwise mal-posed uterus, has not, in the experience of the writer, provided favorable results,

and, employed alone, we unhesitatingly affirm, will often be found inefficient.

Operation by vaginal suture taken through the uterus is inapplicable to many of the examples of displacement, certainly in all of those in which extreme flexion exists, with the womb bound by firm adhesions to the bottom or posterior wall of the cul-de-sac.

In all cases in which retro-deviations are coupled with fixation of the uterus by exudate-membranes, any treatment, to become effective, must include, primarily, the solution of the confining bands.

In the less aggravated cases of the chronic class much may be accomplished often—at first, preferably, through depletion; by punctures or scarification, the employment of glycerine-tampons, iodine and the hot douche; finally, and chiefly, by the prolonged, regular, continuous and careful application of vaginal packings, in the knee-chest posture—using wool-pledgets instead of cotton. Forcible taxis, under anæsthesia, should be employed, in suitable cases, repeatedly, in effort to release the adherent uterus, where the ordinary treatment has failed.

All attempts at solution or rupture of adhesions by indirect methods must, for a considerable number of cases, result in failure; for these, to succeed, the peritoneal cavity must be entered. Abdominal section being for the purpose made, rectifying ventral suture of the uterus, or through, or over its ligaments, is the natural and justifiable sequence.

Here, venturing to assert that ventral fixation of the uterus, in those cases where section of the abdominal wall is a preliminary, is not more hazardous—where proper precautions are observed—than suture, blindly taken, without section, by any of the other methods yet proposed—there remains to be particularly noticed, that a special and very material advantage concerning the final results, is gained by exposure of the pelvic contents to ocular and direct digital inspection. Every operator of much experience can recount a number of instances where, unexpectedly, an occluded and dilated, or distorted and adherent tube, presented, or an invested or diseased ovary. Neglect of like complicating conditions, in operations for prolapse or displacement of the uterus, must, necessarily, most seriously embarrass, often, perhaps, defeat the legitimate results of treatment.

The following cases—all that have been subjected, specially, to treatment for prolapse or displacement, by ventral fixation of the uterus after abdominal section, at the hands of the writer—are reported as contributing in some degree to determine the management appropriate to those of severe sort of their class:

Case 1.—Mrs. F., age 43; widow; multiparous; residence Pittsburgh. When first seen the

swollen and hypertrophied organ rested in complete prolapse between the thighs, exposed mucous surface extensively abraded; condition has existed for eight years; has "not been able to wear any supporter" in the vagina for a long time, because every such trial made her worse. Suffers from all the usual attendant miseries: headache, backache and aching of lower limbs; profuse menstrual and leucorrhœal discharge; vesical and rectal tenesmus, etc.

The uterus being repositd, the tubes were found sacculated and ovaries abnormally sensitive. Castration and hysterorrhaphy were proposed and accepted. After due preparatory treatment operation done May 23, 1889, in presence of and assisted by Drs. Cameron and Sands. Short medium incision. Appendages removed. A single, medium, silver wire suture, carried deeply into anterior wall over body of uterus, bringing uterus and wall into relation at highest possible point; the ends of wire separately armed and carried out through wall on right and on left at lowest part of incision; wounding of bladder avoided; a double catgut ligature was carried through each of the broad ligaments close to the stumps, and passing directly out through abdominal wall. Were tied down at the surface over sections of small rubber tube; the exposed peritoneal surfaces were abraded by lightly scraping with curette, when the wire suture was secured by twisting; incision closed throughout by silver sutures; powdered boracic acid dusted over site of incision and sutures; dry dressing and bandages. The womb suture (silver) was removed on tenth day after—catgut sutures earlier. Wool tampon with boro glyceride was employed for a time in vagina. Patient's recovery prompt. Visited on May 1, 1891. Mrs. F. says: "I am about 25 pounds heavier than at the time of operation, and in better health than at any time before, since my baby was born, over eight years ago. My womb has never come down since the operation, and I suffer from no pain and no annoyance whatever. I do my own housework and washings, now, something I was not for a long while before able to do."

Case 2—Mrs. J. J. W., age 24; nulliparous; residence, Pittsburgh; married 5 years; suffered since before marriage; has very constant backache and pains in lower limbs, and headache; all her pains greatly intensified at every menstrual occasion. Examination shows uterus to be strongly retro-fixed and confined in that position. Patient was treated regularly for almost one year, by the writer, by vaginal packing, also by taxis under ether, and without material improvement. Laparotomy and division of adhesions with suture of womb to anterior wall proposed and accomplished by operation, June 3, 1889. Present, Drs. Emmerling, Sr. and Jr., Prof. Dunn and Dr. Cameron, assisting. Uterus practically excavated

from the rectal pouch; its entire posterior surface bloody from the oozing in consequence of its detachment; bleeding points seared; tubes adherent and occluded at ostia externum, and fimbriæ inverted; tubes were set free and mouths teased open by fingers of operator; ovaries buried in exudate, uncovered without mutilation; no removal of parts. Two silver sutures in womb and through wall; catgut sutures passed to include round ligaments and tied down at surface of abdomen, right and left, as before, over sections of rubber tube. Bladder uninjured in operation; peritoneal surfaces abraded; womb sutures twisted, and incision closed; boracic acid sifted, dry, over site of operation; antiseptic gauze and bandage applied. All sutures removed in ten days. Patient's recovery uninterrupted. The normal position which the womb was made to assume by the operation is since perfectly preserved. This lady, Mrs. W., was last seen by me on May 2, 1891. She was found at her home and her husband's place of business—a busy woman in a bustling restaurant in the city of Pittsburgh—in the kitchen, where she stated she superintended all the cooking, and from very early in the morning until late at night, and daily, and thrived, notwithstanding hard work. She said: "I am well, first-rate; I have no aches nor pains. I change regularly, and without any pain."

Case 3—Mrs. L., aged 47; primip.; residence, Pittsburgh; suffered more or less severely since soon after the birth of her child over eight years ago; especially from lumbar pains; headache, and gastric and intestinal symptoms. Uterus retroflexed.

Operation Feb. 4, 1890; medium incision; right ovary a bunch of small cysts; removed right ovary and its tube. Rectified position of womb and secured same by two silver sutures, taken through womb and wall as in previous cases; catgut sutures, laterally as before described. The sutures were removed in the usual time, but suppuration in the suture tracks occurred; and, eventually, through a fistulous opening which persisted in the right wall, the ligature placed at stump of ovary, escaped. The normal position of the uterus is maintained by that organ. Mrs. L. was interviewed on April 30, 1891. She said: "I have gained in weight, and I do not suffer with my head at all, as formerly; in this respect I am a great deal better—otherwise I cannot say that I have gained. I am regular."

Case 4.—Mrs. J. H. L., æt. 28; primiparous; residence Allegheny; has a very deep bi-lateral laceration of cervix uteri; relaxation of vaginal outlet and complete prolapsus uteri; has been over three years in present state. May, 1890, operated for restoration of cervix and vaginal walls. Result: September 22, 1890, complete and thoroughly satisfactory repair of cervix and ample closure of vulvar opening, but, when patient,

standing, strongly exerts herself in "forcing" the uterus, that organ descends to the level of the labiae. September 22, 1890, operation by laparotomy and suture as in cases 1, 2 and 3 detailed. Two silver wire womb sutures and two catgut sutures over each ligamentum rotunda; no mutilation of parts; incision closed and wound dressed as before. Sutures removed in the usual time. Examination of the synoptic chart preserved in this case shows in most remarkable manner how slight the disturbance following this operation may be in well conducted cases. The highest temperature noted during the times for which the record is kept occurred on the evening of the first day, and was $99\frac{1}{3}^{\circ}$ F.; the highest pulse rate 100, same date and same hour. Opium was withheld. Nor was there sufficient pain, as a result of the operation, at any time, to make excuse for its use possible. The intestine was regularly and freely evacuated by the use of calomel and drastic enemata. The patient was permitted to relieve herself of urine over the pan. The cases were all treated at their homes, but nursed by intelligent and trained nurses. The strictest aseptic precautions were in all respects observed.

The first, second, and last cases offer us good examples of their kind where this important surgical interference is demanded, and the test of efficiency of method has been, for each one of these operations, severely tried; and we may now claim reasonably that sufficient time has elapsed to enable us to claim cures. The remaining case was probably not so carefully selected for operation, and not so well understood, partaking in its character of neuroses derived through gastric derangement and digestive disorder.

THE AFTER-TREATMENT OF CASES OF ABDOMINAL SECTION.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 1891.

BY CHARLES P. NOBLE, M.D.,

SURGEON IN CHARGE OF KENSINGTON HOSPITAL FOR WOMEN, PHILADELPHIA.

According to Oliver Wendell Holmes, to successfully treat an individual one should begin with the grandfather. The same principle applies to the successful after-treatment of cases of abdominal section. Whenever possible, careful preparatory treatment should be carried out. Nutrition should be improved, when depraved; the excretories should be made active, especially the bowels and skin. Operation should be rapid, careful and thorough. Diseased, and especially suppurating, structures should receive most careful attention, and unless vital, organs be completely removed. Asepsis in clean operations, and irrigation and drainage in dirty operations,

are essentials. Under such conditions, unless operation has been made a last resort, or the vital organs of the individual are seriously crippled, proper after-treatment of cases of abdominal section will insure a successful result quite uniformly.

That which is accomplished by after-treatment in cases of abdominal section is principally of a negative character. The object is to protect the patient from all sources of danger, while nature does her perfect work. The most positive ends accomplished are: to sustain the powers of life to enable the patient to pass a crisis; to keep the excretories active; and to prevent wound secretions from becoming a source of poison.

The after-treatment of typical cases of abdominal section is extremely simple. By typical cases I mean those in which the operation has been done satisfactorily, without special loss of blood, and in which the patient goes to bed without marked shock.

The room in which the patient is to remain should be airy, well lighted, and ventilated. The bed, preferably should be single, and of such a height that the woven wire mattress is two feet above the floor. A hair mattress is the best. The bed should be made warm during the operation by having hot water cans or bottles placed in it. These should remain about the patient until reaction is complete—care being taken to avoid burning the patient.

Diet.—During the first twenty-four hours nothing should be given. Rinsing the mouth with water will relieve thirst partly. If thirst is excessive, enemata of beef tea, eight ounces or a pint, may be given every four hours. This should relieve systemic thirst; but it will not relieve thirst due to a dry mouth or throat. On the second day one or two drachms of water every half hour may be given, to be increased or withheld according to the tolerance of the stomach. After thirty-six or forty-eight hours beef tea, one or two drachms, or an equal amount of milk and lime water or soda water may be given; and increased if well borne, the frequency of administration being decreased. If all goes well, on the fourth or fifth day water, practically *ad libitum*, may be given. After a week soft diet may be given, and after two weeks full diet.

Drainage Tube, and the Abdominal Wound.—In my judgment the drainage tube should be used unless there is some special contra-indication. If the drainage is not excessive, nor bleeding going on, it is best to surround the tube with sterilized cotton; with the bandage over all. In this way the tube is protected against infection between dressings. A rope of bi-chloride wet gauze should be passed down the tube to Douglas' pouch, and extend externally into the absorbent cotton. Used in this way most of the fluid poured out into the pelvis will escape by

capillary action, and draining the tube will be unnecessary more than twice or three times in twenty-four hours. In this way the tube can be managed by the surgeon. All soiled cotton should be removed at each dressing, and the outside of the tube be kept aseptic by washing with sublimate solution. It is well also to keep the gauze over the wound wet with bi-chloride solution, until the tube is removed. In draining the tube, the rope of gauze is removed, a pledget of aseptic cotton is seized with an aseptic forceps and passed down the tube. This is repeated until all fluid is removed. When the pelvis has been made dry, it is well to pass one pledget saturated with sublimate solution. The wet sublimate gauze drain is next inserted, and the cotton and bandage readjusted. This method of managing the tube has given perfect satisfaction in typical cases.

When drainage is excessive or hæmorrhage is going on, it is better to use the rubber dam about the tube, having it project through the bandage; this way it is more accessible for draining. The chances of infection are also greater. In this class of cases the tube must be drained often—even every fifteen or thirty minutes in case of bleeding. The piston syringe may be used to remove fluid; but I have found it unsatisfactory. It will not remove all fluid from Douglass' pouch.

The tube should be removed when the drainage ceases to saturate the gauze rope in the tube, especially if the drainage has become serous. In most cases the tube will remain in from one to three days. When the tube is removed early, the wound should be closed by tying a provisional stitch introduced during the operation. If for any reason it has been necessary to use the tube five or six days or more, it should be elevated from day to day, perhaps a shorter one substituted, and finally a plug of gauze, inserted through the abdominal wound, be used. In this way a sinus can at times be prevented. In such cases the judicious use of sublimate solution, and the peroxide of hydrogen solution within the tube track is of great value. These agents should be used on cotton carried down the tube in the grasp of a forceps.

The hands of the surgeon must be made aseptic before each dressing of the tube, and the tube forceps must be kept aseptic. By having the forceps well nickle-plated it can be washed before use in sublimate solution. After use it should be carefully washed with soap and water. With a little practice the surgeon can drain the tube with but little use of his fingers. Only the thumb and forefinger of the left hand need come in contact with the cotton or that part of the tube forceps which passes down the tube. The method employed is as follows: small rolls of absorbent cotton are wrapped in tissue paper, and sterilized

in the steam sterilizer. A roll of cotton partly unwrapped is held by the nurse, the tissue paper serving to keep her fingers from touching the cotton. A pledget of cotton is seized by the tube forceps, lightly wrapped about the forceps by the thumb and index finger of the left hand, and then passed down the tube. It may or may not be necessary to steady the tube. The process is repeated until the pelvis is dry. It is manifest that if special care is taken in cleaning one thumb and forefinger that asepsis can be maintained. And this can be done with little expenditure of time.

A satisfactory method of dressing the wound is to use a wet sublimate gauze dressing until the tube is removed, and then to apply a powder consisting of iodoform one part, and boric acid seven parts. The deep sutures should be removed on the seventh or eighth day; at which time the wound should be supported with adhesive straps. Some days later the superficial stitches may be taken out.

The Bladder.—It is best to encourage the patient to void urine. When necessary the catheter must be used. Every care should be taken to avoid catheter cystitis. This is best accomplished by using a glass catheter, having it carefully washed in running water after use, and kept in sublimate solution until needed again. Before the catheter is used the vestibule should be wiped dry with absorbent cotton. Then the catheter, properly lubricated with vaseline, should be introduced, the parts being exposed.

The Bowels.—The bowels should be moved early—the second or third day. I believe that the pain after abdominal section is largely intestinal—due to flatus, or to irregular peristalsis—and that the best way to relieve it, is to open the bowels. The plan of giving a brisk cathartic shortly before operation so as to secure an early evacuation of the bowels, commends itself to my judgment, though I have not employed it. On the second or third day an enema is given; and should this fail, calomel in twelfth-grain doses, every half hour, or concentrated citrate of magnesia solution. (Four ounces equals one pint of official). Epsom and rochelle salts have proved too nauseating for my patients.

As an enema the following is used: Magnesia sulphet., two ounces. Ol. terebinth, one-half ounce. Glycerini, two ounces. Aquæ, q. s. ad., four ounces. This mixture is a very reliable purgative enema.

The bowels should be kept open at least on alternate days throughout the convalescence. Special care should be taken to prevent the accumulation of scybalous masses.

General Care, especially by the Nurse.—During the first few days, or period of thirst and pain, the patient should be encouraged to bear up, and be told that pain is quite the rule after abdomi-

nal section. Nervous, fretful patients must be impressed with the fact that nothing will be given that is not thought good for them, and that personal teasing appeals will avail nothing. As a rule, a good *morale* can be thus established. The nurse can do much to promote the comfort of the patient. During the period of thirst the face and hands should be bathed frequently with ice water or cold water and alcohol. And the mouth should be rinsed frequently with ice water or a weak solution of permanganate of potassium, or of peroxide of hydrogen. Glycerine and ice water will at times relieve "dry mouth" but generally the sweet taste of the glycerine is objectionable. The nurse should be given the rectal tube, and should use it whenever pain from flatus is present.

The bed ought to be kept strictly clean, and the sheets be kept smooth. The draw sheets and the bandages should be changed at least twice daily. The patient's back should be rubbed well with alcohol or soap liniment two or three times daily. She should be allowed to flex the legs and thighs, when the legs can be comfortably supported by placing a small pillow under the knees. Cotton wool pads or an air cushion should be provided to ease the back. Attention to these details adds much to a patient's comfort.

I believe that it is best to keep patients on their backs for two weeks after abdominal section. During the first week comfort is best attained by avoiding all motion. After eight or ten days the use of the bed rest permits sufficient change in position. After three weeks the patient may be permitted to sit up in bed. Hernias are best avoided by careful suturing, and by rest until firm union has occurred.

COMPLICATED CASES.

Shock.—Shock is met best by the application of external heat, the use of strychnia, digitalis, caffeine, and whisky hypodermically, and of decoction of coffee or beef tea by rectal enema. Within eight hours, thirty minims of the tr. of digitalis, one-eighth of a grain of sulphate of strychnia, and two or three grains of the citrate of caffeine may be given. If recovery is not prompt, one-half of a grain of the sulphate of strychnia, and one drachm of tr. of digitalis may be given in twenty-four hours, and an enema of beef tea, eight ounces to one pint, with whisky, one or two ounces, may be given every two or four hours. This treatment can be continued for some days. If much blood has been lost, large amounts of fluid will be absorbed from the rectum. A saline solution, also, may be injected into the areolar tissue under the skin. After one or two days, if rectal feeding is necessary, a more nutritious mixture should be substituted. I have used the following:

One egg; milk eight ounces; peptonize and add whisky one or two ounces. This quantity can be given by enema every six hours. If rectal feeding is kept up for many days, it is well to wash out the rectum daily with soap suds, so as to remove decomposing material, and prevent proctitis.

Vomiting.—Vomiting from ether cures itself. When vomiting continues more than two days, some other cause must be sought. If not excessive, vomiting will usually cease if no fluids are given by the mouth. A mustard plaster over the epigastrium, or a tumbler full of hot water will at times arrest it. If simple means fail, it will be found that the vomiting is due to peritonitis, or to impending obstruction of the bowels. In either case the bowels should be moved at all hazards. This is accomplished best by the use of the purgative enema already noted, given if necessary through the rectal tube into the colon. Broken doses of calomel can be given when other purgatives are rejected. Concentrated solution of citrate of magnesia, and seidlitz powders also can be used. The continued use of these agents usually will open the bowels. Secondary abdominal section for the relief of obstruction should not be undertaken too quickly, as not infrequently the bowels are moved only after repeated efforts; and moreover, the results of the secondary operation are not encouraging.

Fever.—When fever occurs the bowels should be kept freely open, and the body be sponged freely with cool water. The use of antipyretics is of doubtful value. When to re-open the abdomen for peritonitis, and when to trust to medical measures is a difficult problem. In general, when the skin is dry, the face flushed, and the pulse full and bounding, secondary operation will be unnecessary; but when the skin is "leaky," the extremities cool, and the pulse rapid and feeble, absorption of septic material is going on and operation is indicated. Unfortunately, the result usually is death.

Opium.—The use of opium in any form in typical cases of abdominal section is unnecessary. A little encouragement during the first day or two will enable the patient to stand the pain, and later it is quite bearable. Occasionally morphia is useful when a nervous patient becomes much excited and cannot otherwise be controlled. I feel convinced that the experience of the past few years has demonstrated the fallacy of the doctrine that opium is curative in peritonitis; and that it finds its legitimate field in abdominal surgery in combating extreme nervous excitation, and in easing the last hours of the dying. Occasionally it may be used temporarily to relieve extreme pain.

Asthenia.—Asthenia must be combatted by the systematic use of nutritive enemata with whisky, together with the administration of such liquid

food as the stomach will bear. Champagne can often be given with advantage when other stimulants are rejected. Less can be done to combat asthenia by alimentation and medication after abdominal section than after other operations, because as a rule the stomach is not available. The fate of the patient is decided, in general, when the operation is completed.

"PYOKTANIN" AS AN ANTISEPTIC.

Read by Title in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY H. J. BOLDT, M.D.,
OF NEW YORK.

PROFESSOR OF GYNECOLOGY, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; GYNECOLOGIST TO ST. MARK'S HOSPITAL AND THE GERMAN POLYKLINIK.

Among the remedies introduced as antiseptics lately, is one called pyoktanin, of which Prof. Dr. J. Stilling, of Strasburg, is the discoverer. The advantages claimed for this analine compound are that, 1, it is devoid of any injurious effect on the human economy or organism; 2, certainly and utterly destructive of all bacteria or other microorganisms absorbing it; and 3, that it is rapidly diffusible in, and permeant of, both healthy and diseased animal tissues or fluids, and perfectly penetrant through the enveloping membranes and internal substance of all bacterial colonies harbored by them.

The respective remedy, which is manufactured by E. Merck & Co., has been given a thorough trial by me in suitable cases for but a comparatively short time, but even with so short a trial, it has impressed me very favorably. The suppuration ceases more rapidly under its influence than under the use of other remedies, and that without producing any noticeable unpleasant effect on the system.

Stitch hole abscesses, two sinuses with thick pyogenic membranes, and purulent endometritis, were the conditions for which it has been put to use, employing a 1 per cent. watery solution, which is five to ten times stronger than recommended. Such strong solutions were used because those as recommended did not seem to me to do any better service, after a few trials, than some of our other antiseptics, which had the advantage of not discoloring everything with which they come in contact, that being the main disagreeable feature in connection with the use of pyoktanin—the discoloration produced being a deep purple, which can only be immediately removed from the hands by washing with soap liniment or javelle water. Clothing, etc., is destroyed by the stains, or the use of the javelle water required for washing them, hence some care must be exercised in its use. This unpleasant feature can, however, not come into consideration, if we remember that the conditions for which I have used

it are of very obstinate character, and withstand our ordinary remedies with a tenacity which sometimes brings us to despair, with pyoktanin applications I have seen them yield almost invariably with ten to twenty daily applications. In the more mild forms, as stitch hole abscesses, three or four days sufficed to bring suppuration to cessation.

In the form of endometritis mentioned, the remedy is injected directly into the uterus with a Braun syringe, and so far, none of the unpleasant effects have been noticed which we are apt to see from iodine, etc. 1, the cervical canal is always patent in such conditions, so that over-distension, if the injection is carefully made, never occurs; and 2, the remedy is non-irritant.

I have briefly stated my own personal experience, thereby hoping to stimulate my colleagues for a further trial. In carcinoma, for which it is also used very extensively, my experience is yet too limited to speak one way or the other.

IRON IN LARGE QUANTITY IN ANEMIA.—In a very marked case of anemia in a young girl of 19. H. Taylor, after being assured of the satisfactory condition of the digestive functions, prescribed for her a drink of a diluted solution of the perchloride of iron (v-xxv drops to 30 cc. (3j) of water). He gave her to understand that the more she took day and night, the better it would be for her, and the sooner would she recover. She entered heartily into his plans, and in twenty-seven days took almost 900 grams (3xxx) of tincture of the perchloride of iron (according to the British Pharmacopœia), instead of 100 grams, the maximum dose with most physicians. There were no unpleasant phenomena on the part of the digestive tract. To keep the bowels regular, he gave daily a pill of aloes and nuxvomica. The result was complete cure after four weeks of treatment. The author recommends this mode of treatment, which allows the ingestion of large quantities of iron, without in any way interfering with the health of the patient. Should the iron commence to show any unfavorable effects (constipation, etc.), the patient should stop the medication, which no longer agrees with him.—*La Courrier Médicale; La Gazette Médicale de Montréal.*

UNIQUE PROCEDURE IN A CASE OF PHOTOPHOBIA.—A boy of 13 was affected with a panniform keratitis of both sides, with intense photophobia. Each time that the pupils were exposed to bright light, the boy was seized with violent sneezing. A pledget of cotton charged with a few drops of chloroform was introduced into the external auditory meatus and in a few minutes the eye could be opened without the occurrence of sneezing. The author (Gutteriez-Ponce) explains the effects of this local medication by anesthesia of the Gassenian ganglion which is situated in the neighborhood of the auditing canal. This ganglion might be the center of the reflex action giving rise to the sneezing, consecutive to the impression on the retina by a bright light.—*Journal de Médecine de Paris.*

A BOUNTY of one hundred francs is offered to every married couple in France who shall add one more citizen to the State during 1892. It is hoped in this way to check the decrease in the French population.

PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to
JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,

CHICAGO, ILLINOIS.

All members of the Association should send their Annual *Dues* to the *Treasurer*, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

BY-LAW IV.—THE PUBLICATION OF PAPERS AND
REPORTS.

No report or other paper shall be entitled to publication in the volume for the year in which it shall be presented to the Association, unless it be placed in the hands of the Board of Trustees on or before the first day of July. It must also be so prepared as to require no material alteration or addition at the hands of its author.

Authors of papers are required to return their proofs within two weeks after their reception; otherwise they will be passed over and omitted from the volume.

Every paper received by this Association and ordered to be published, and all plates or other means of illustration, shall be considered the exclusive property of the Association, and shall be published and sold for the exclusive benefit of the Association.

The Board of Trustees shall have full discretionary power to omit from the published *Transactions*, in part or in whole, any paper that may be referred to it by the Association, or either of the Sections, unless specially instructed to the contrary by vote of the Association.

SATURDAY, JULY 11, 1891.

ELIMINATION.

It may be accepted as true that microorganisms do their work by means of their chemical products. Whether their products be formed within or without the body, if they once gain admission to the blood stream they have full opportunity to produce their peculiar symptoms. Until suitable means shall have been provided for directly attacking the microorganisms themselves, there remain but two avenues of curative treatment open, viz.: the neutralization, and elimination of their chemical products. Leaving for the present the work of neutralization to the liver, the question of elimination presents itself as the one more easy of solution. Looking back to our fathers in medicine, whom perhaps we are too prone to neglect, we are at once impressed with the attention which they paid to this subject. Attend first to the *primæ viæ*, was their great watchword. Their purgatives and emetics, their calomel and tartar emetic, were used much more intelligently than we use them to-day. Venesection was probably in most instances an eliminative procedure, and although now entirely out of fashion, it is fair to prophesy that it will soon again hold an honored place as a thera-

peutic measure, even if it must gain this place indirectly through the channel of relief to purely mechanical conditions of the circulation, as exemplified in the recent paper of Dr. H. A. Laffleur (*Med. News*, Vol. LIX., p. 5). In addition to the three great eliminative channels, the kidneys, the skin and the bowels, attention should be directed to the lesser or secondary channels.

To what extent respiration is eliminative is not established, although the poisonous properties of the expired air have long been known, yet it is probably true that the nervous symptoms which occur in the pneumonias, are partly, if not entirely, due to the mechanical limitation of this particular eliminative channel. Running sores are no doubt important means of elimination as well as possible sources of infection, and the layman's idea of the danger attendant upon the sudden healing of those old wounds, may not be entirely without foundation.

To what extent may one channel of elimination be substituted for another? Every practitioner knows only too well that the bowels as stimulated by active purgatives, and the skin as excited by the hot bath, and pilocarpin, furnish but a partial substitute for the kidneys. But does it follow that the channels themselves are at fault and that the means of stimulating them is of secondary importance? Should the channels alone be considered, or should they be thought of in connection with the means by which they are opened? The sweating produced by pilocarpin differs apparently in no way from the sweating which follows the use of antipyrin, acetanilid, or any other of our modern, so-called, antipyretics. Yet the results following the two remedies are essentially different. Ignoring the other actions of the antipyretic it is quite possible, nay probable, that the antipyretic sweat carries away other substances than does the pilocarpin sweat.

The blister as a means of securing elimination through the skin is in frequent use, but not so frequent as its importance warrants, while cups are relegated to the barber. Leeches are occasionally employed, but venesection dares not even lift its head.

To inflict a wound, for a medical rather than a surgical reason, would probably be considered cruel, and to even mention a seton in these days of asepsis, might lead to professional ostracism.

Nevertheless if elimination is to do its best for humanity, it must be studied broadly, and all phases of it utilized.

The interchangability of the several eliminative channels must be more carefully studied, the best channel, or channels, to appeal to in given conditions, and the best means of opening these channels under the particular circumstances, must be worked out at the bedside, and finally those neglected means of elimination, whose assistance at a critical moment may save life, must be resurrected, and the despised blister, lancet, and seton again called back to active use, and again given their proper sphere.

SCIENCE COURSES PREPARATORY TO MEDICINE.

In a recent number of *THE JOURNAL* was published a circular sent out by the Illinois State Board of Health to about 200 literary and medical schools in the United States. We learn from the Board that about twenty-five literary institutions have already adopted, or signified their willingness to adopt, science courses leading to the study of medicine. It is gratifying to note, that in addition to some large universities, some of the smaller colleges have recognized the fact that a young man must have a special training in science to be prepared for the study of medicine.

It has been objected to courses preparatory to the study of medicine, and even to higher medical education, that the people have not yet demanded scientific physicians. This is not entirely true. The representative newspapers of the country are demanding better educated physicians, and in any event, the medical profession must take the lead in this matter. The longer and better courses of study in the medical colleges are due to prolonged agitation, begun by the medical profession. The same will be true of whatever is done in the way of establishing science courses preparatory to medicine. That such courses are profitable no one can doubt. The President of Tulane University of Louisiana writes: "The College and University give every one the opportunity to go to the medical college prepared. When they do so, they always succeed in taking the prizes of the medical department, the posts of resident students in the

Charity Hospital, twenty-eight in number. All who have tried have, on competitive examination, taken a resident's place."

The statement made by President Johnson is confirmatory of the opinion of thinking men, that after an ordinary high school or classical course the young man is not prepared to begin the study of medicine, while a proper science course gives the needed preparation; and that the student who takes such a course gains a liberal education—as liberal as that offered by any classical course. As was aptly pointed out by Dr. Gardiner in his presidential address before the British Medical Association a few years ago, the physician must be a naturalist, a student of nature, and the foundation of his knowledge must be laid in scientific studies. There is no good argument against science courses, preparatory to the study of medicine, and it is gratifying to know that some of the literary institutions are taking up the matter so earnestly. They would not have done so had they not recognized a demand for such courses and a demand for better educated physicians. The drift of human thought is more and more toward pure science and its application to human progress.

HIGHER MEDICAL EDUCATION.

The cause keeps marching on. At the late meeting of the Indiana State Medical Society, the following preamble and resolution were adopted:

WHEREAS, Responding to the demand for advanced and thorough medical education, the schools of regular medicine in Indiana have made compulsory on all students matriculating for the first time after this date, as a pre-requisite to graduation, four years' study of medicine, and three full courses of lectures of six months each, therefore,

Resolved, That this Society heartily endorses such action, and, as a matter of simple justice to those schools who have taken this advanced position, we respectfully request the authorities of this State to consider and class medical schools, who demand less than the above requirements, as institutions not reputable, and their diplomas unworthy of recognition.

N. D. COX, M.D.

WM. FREEMAN, M.D.

Unanimously adopted.

We are pleased to also announce that the Indiana State Board of Health are in full sympathy with the above, and will take similar action as one of the standards of requirement.

DR. JOHN H. RAUCH.

At the last meeting of the Illinois State Board of Health, this veteran official tendered his resignation as Secretary of the Board. For more than a quarter of a century DR. RAUCH has given a whole hearted and enthusiastic service to the cause of sanitary science, and to an elevation of the standard of medical education and practice. In these departments his labors have been characterized by such ability and good judgment as to win the plaudits of right thinking men on two continents. That he has been untiring and indefatigable in the prosecution of his plans, there can be no question; their accomplishment is known to the world.

In noting the recent action of the Kentucky State Board of Health, and of the Indiana State Medical Society, we could not but feel that the sentiment back of their resolutions, was largely due to the work that is now laid down by this honored servant of his profession and the public. At the same time we thought of the sense of profound satisfaction that must fill his soul as he contemplates the grand results which have been achieved, and to so great an extent through the instrumentality of his own work.

EDITORIAL NOTES AND ITEMS.

NEW EFFERVESCENT PREPARATIONS.—Among the granular effervescent preparations, recently brought out in England, are the following: Citrate of caffein, three grains to the drachm; salicylate of soda, ten grains to the drachm; sulphur compound according to Garrod's formula; and cascara sagrada, two grains in each drachm. The *Lancet* reports that an analytical examination has been made, which shows that the weights and proportions were correct as claimed by the makers. The preparations were found to be readily soluble, and the granulation of them had been accomplished with all necessary care. These appear to be especially acceptable to children, who will often take a preparation that "fizzes"—as they say—although the drug contained in it may be anything but pleasant to the taste.

THE BOARD OF HEALTH OF NEW YORK CITY.—Col. Emmons Clark, the experienced secretary of the Board of Health of New York City, has contributed to the *Popular Science Monthly Magazine* a history of the workings of that Board

during the quarter-century during which the author has been officially connected with sanitary administration. Although a trifle bureaucratic and colorless in its composition, Col. Clark's sketch is a model of condensation, and will interest report-making sanitarians all the world over. A few lines comprise, oftentimes, the work of years and the best efforts of a regiment of toilers. The great city of which he writes was virtually devoid of any sanitary administration until 1866, when the popular dread of an epidemic of cholera compelled the enactment of an efficient sanitary police law. Since that time the Board has been remodeled from time to time in the interests of "hungry politicians," but there have always been some good and honest workers in its service. Progress, amid many interruptions and in spite of many discouragements, has been the rule. Some of the earlier printed annual reports of the Board are extremely valuable. The accomplishment of the Board in regard to the check and regulation of infectious diseases, appears to have been the strongest single feature of its work. One of the peculiarities in the New York Board is the fact, the law forbids that a medical man shall be its president. A chemist or a cotton broker may become the sanitary standard-bearer of the metropolis, but a physician never. But the law may be changed before many years have passed by, possibly at the next session of the State Legislature. The present enactment is an anachronism from the medical standpoint, and will undoubtedly soon be rescinded.

HONORS.—The degree of LL.D. has been conferred by Wabash College upon Dr. Joseph Eastman, of Indianapolis. The same degree has also been conferred by the University of South Carolina upon Dr. F. Peyre Porcher, of Charleston.

"IT HAS recently been ascertained that the vapor of vitriolic ether, when inhaled into the lungs, produces effects upon the brain and nervous system similar to those of nitrous oxide gas. This fact was no sooner made public than a thousand experimenters started up, including all ages and both sexes. The smell of ether prevailed everywhere. Even the little school-boys were seen clubbing their pennies to purchase a vial of the exhilarating fluid, which was put into a paper bladder and eagerly passed from one to another, in some unfrequented spot. We

might, perhaps, feel amused at the ridiculous capers supposed to be cut by those groups, had no serious consequences resulted from it. But having ourselves witnessed the serious indisposition of several young ladies, which could be ascribed to breathing ether, and read of two well attested cases in which the practice proved fatal, it behooves us to condemn the use of the fluid by inhalation as highly pernicious and dangerous."—(Portfolio by Oliver Oldschool, Esq., July, 1824, p. 326.)

AN OPHTHALMIC HOSPITAL IN CINCINNATI.—Dr. Robert Sattler has given a valuable property for the establishment of this institution. A staff and dispensary service have been organized, and arrangements made for giving special instruction to students.

DOMESTIC CORRESPONDENCE.

Diphtheria.

To the Editor.—Some twelve or fifteen years ago I wrote an article on diphtheria which was published in a local paper, claiming it to be an affection of the pneumo-gastric nerve. And now, after long and careful observation, I am impelled not only to confirm that earlier statement, but to add to it the result of maturer consideration by bringing to your notice a more detailed account of my idea of this troublesome disease.

I believe the entire eighth pair of nerves to be affected. I believe the diphtheria microbe or bacterium to have an especial affinity for this pair of nerves, causing an inflammation of them, affecting particularly the glosso-pharyngeal and pneumo-gastric; but involving also, occasionally, the spinal accessory.

If any medical gentleman will spend two hours in refreshing his memory on the exact distribution of the two first named, and then sit by the side of a patient suffering from diphtheria and carefully compare the location of the affected parts with the distribution of these nerves, I think he will come to the same conclusion.

As to the false membrane, I have always regarded it as a passive exudation caused by the loss of nerve force of the capillaries of the parts from which it exudes. One of the first and most positive diagnostic symptoms of diphtheria is the enlarged tonsil covered with false membrane. Gray says as to the anatomy of the tonsil: "Its inner surface presents from twelve to fifteen orifices, leading into small recesses, from which numerous follicles branch into the substance of the gland. These follicles are lined by a continuation of the mucous membrane of the pharynx covered with epithelium, their walls being formed by a layer of closed capsules imbedded in the sub-mucous tissue. The capsules are analagous to those of Peyer's glands. They contain a thick, greyish secre-

tion. The nerves are derived from the fifth and the glosso-pharyngeal."

Now, is it not reasonable to believe that the loss of contractile force of the small nerves of the tonsil from the inflammation of the parent nerve, together with the devastations of the microbe in the tonsil, largely increase the "greyish secretion," and that this exuding through the "twelve or fifteen orifices," has something to do with the formation of the false membrane? That looks reasonable to me and I believe it to be the true source of this false membrane, as well as of all that found in this nerve tract. I believe these exudations to be similar to the petechial exudations over the chest and abdominal regions in cerebro-spinal meningitis, typhus and low grades of typhoid fever. When the spinal cord is implicated exudation takes place from want of nerve contractile force of the peripheral aspect of the spinal nerves and forms in scales, nodules, etc., of various sizes and appearances.

Treatment.—The problem of treatment may be readily formulated. If the streptococcus of diphtheria selects the eighth pair of nerves and branches for its terrible ravages, have we a germicide with an equal affinity for the same region? I am ready with an emphatic Yes! We undoubtedly have such a germicide in the different preparations of mercury, especially calomel. The uniform success of the treatment which I have adopted is the rock on which I found this statement.

Calomel was used with success as far back as 1825, although physicians of that date had no idea of the reason for this success with that specific, nor has, hitherto, any explanation been attempted. I quote from the London Medical Repository of December, 1826, page 499:

"Mercury, which seems to exert a direct and almost specific influence upon inflammation of the mucous membrane of the throat and air passages, has been highly extolled by the French physicians in the treatment of diphtheria. It was first employed by Dr. W. Connolly, of Chettenham, then resident physician at Tours, and with such success, invariable, that the French practitioners, although with some reluctance, adopted it in their practice. To secure it success the full mercurial influence is necessary; with this object, two grains of calomel are to be given every two hours."

In my own practice I have adopted the following:

I give from one to five grains of calomel every five hours, according to the age of the patient, with no other treatment except cleanliness and good nursing.

The medicine is easy of administration by putting it on the tongue and giving a sip of water.

I think two or three brisk operations on the bowels, a day, beneficial for the first two or three days, but should the cathartic effect be too great it is easily checked by a little Dover powder. It is surprising what an amelioration of all symptoms takes place after three to five days of this treatment. The false membrane dissolves and disappears, the microbes become inert from the specific action of the mercurial poison, the temperature becomes normal, the pain and swelling are gone, the appetite returns, and above all, that unaccountable nausea and vomiting, which follow a week or ten days in the wake of

diphtheria, never put in an appearance. More than all, I have yet to see a case of paralysis of even the soft palate follow diphtheria when this treatment has been adhered to from the beginning. When called to see a diphtheria patient, in addition to above treatment I give to other children of the family that have been exposed to contagion, from one to four (according to age) one-tenth grain calomel pills every five hours for two or three days as a preventive, with uniform success, a large majority thus treated escaping the disease or suffering only a light touch of it, the germicide entirely protecting those parts usually affected by diphtheria.

Do not be afraid of the calomel. The verge of ptialism must be reached in order to secure the best results.

We do not fear salivation now as we did when I first began the practice of medicine, over fifty years ago. At that time we could not control it: now, with chlorate of potash, we regulate it with absolute certainty.

If medical gentlemen who have the opportunity of making post-mortems upon patients having died of diphtheria will thoroughly investigate the changes that have taken place in the eighth pair of nerves, and, if it presents the appearances which I believe it will, my theory will be perfectly established, at least in my own mind, and I shall feel greatly indebted to them if they will report the same to me or to THE JOURNAL of the Association.

DR. W. R. McMAHON.

No. 312 South Front street, Mankato, Minn.

Forced Respiration. Letter from Dr. Fell.

To the Editor:—Your correspondent, Dr. Herzog, of Hoboken, N. J., leads me to believe from the tenor of his article on "Forced Respiration," in the May 9th number of THE JOURNAL, that he has not read my address upon this subject with that care which it deserved. Had he done so, I am inclined to believe that so much of the valuable space of THE JOURNAL would not have been given to the elaborate account of an instrument which undoubtedly was never used to save human life; or, if it had been, it would likely have failed ingloriously. I will not now be surprised if some one should add that Hippocrates had thought of forced respiration, and even devised an apparatus to perform it with. John Hunter did both, and possibly others, but we have no record of any of these noted men having applied their invention to the saving of human life. See Prof. Horatio C. Wood's remarks in his address before the Berlin Congress, in which he says: "but I have not found that either Hunter or Richardson treated by forced artificial respiration, an actual case of disease or poisoning."

In all this apparatus a grave defect existed, in my opinion, in that provision was made to exhaust the air from the lungs; this complicates the apparatus, and, furthermore, is not in accord with physiological conditions, as inspiration is a forcible measure, while expiration, being passive and produced by the elasticity of the fibro-elastic tissue of the lungs, does not call for the utilization of mechanical means to produce it. I also believe that an apparatus provided with means for ex-

hausting air from the lungs, would prove a very dangerous instrument to place in the hands of the average physician in an emergency case.

However, no one will question that Richardson, Hunter, the designer of the apparatus mentioned in Dr. Herzog's letter, and several others whom I could cite, have prepared or invented instruments for forced respiration upon human beings.

With all their labor, what did they accomplish? Was a single human life saved by them? Did they demonstrate the wonderful possibilities of the method? Let us see. After my first operation with the instrument used in my physiological laboratory, and with which, notwithstanding its defects or adaptation for the purpose, I had succeeded in keeping my patient alive for nearly three hours, until he breathed for himself, I looked up the home and foreign literature on the subject. Nothing was discovered which appeared to controvert the fact, that I was justly entitled to the credit of being the first to systematically and practically solve the question of the value of forced respiration in the saving of human life; or that I had demonstrated, as one physician puts it, "that air can be forced into the lungs without any damage to them." Whatever has been accomplished, also should be stated, was without any previous knowledge of the failures in the same field, which had antedated my efforts.

I can say, with the practical knowledge obtained from operating upon human beings, that the instruments used in the physiological laboratory do not meet the conditions to be successfully overcome in breathing for a human being for any length of time. They may answer in some instances as a make shift, but the work is carried on at a great disadvantage, and with many chances in favor of producing, instead of averting, a fatal result. They were never intended to be used upon human beings. The instrument originally devised by myself in all its practical details, and with which the results tersely detailed at the end of this letter were accomplished, was founded upon the experience obtained in my first case, and the results of my labor with it so overwhelmingly annihilates any controversy in opposition to its use, that it is needless to do more than present them to the profession. Had similar results or demonstrations been accomplished at the hands of others in the past, nothing could have prevented them from receiving the widest publicity in the medical literature of the day, but no record is found which detracts from the practical value and originality of my labors. As a physiologist, I was acquainted with the apparatus used in the physiological laboratory, from the simple bellows with nozzle poked into the trachea of a dog, to the more complicated constant Sprengle blower with interruptor, which admittedly would be of no use as an emergency instrument.

The apparatus I have used meets all requirements for forced respiration in man, with or without tracheotomy, and in the *simplest manner*. It covers all the methods which can be utilized in the operation, is adapted to be used out of doors or in a cold atmosphere, but may be modified by an arrangement to provide a constant air supply and automatic inspirator, which would, however,

increase the cost, and do away with the emergency feature of the apparatus, as now used.

Dr. Herzog's article, possibly without intent, would naturally lead to the inference that the subject is old, not worth considering; its tenor is not uncertain. The truth is that the work in forced respiration, prior to my own, and running through the past century to a great extent, had simply relegated it to the list of unjustifiable procedures. Do we find anything previous based upon results recommending us to use forced respiration after all other methods of artificial respiration had failed? On the contrary, we do find in every medical work treating on the subject, the "Ready Method in Asphyxia of Marshall Hall," the highest accepted authority, that we must avoid the use of bellows or any forcing instrument.

Now I propose to talk plain, as it seems entirely unnecessary at this late date to mince words upon this subject. The practical introduction to the world of the value of forced respiration in the saving of human life, the demonstrations which indicated its great possibilities, must be accredited to an American, and the work of others in the past had nothing to do with the results which were original in conception and practical application.

The question simply amounts to the difference between failure and success; will the credit be accorded to those who failed or the one who succeeded? If Columbus had prepared his ships, but not sailed across the Atlantic, would he have discovered America?

What also must be admitted by those who are inclined to accord justice to whom it is due, is that the practice of vivisection in the colleges and laboratories of the land, had no relation whatever to the saving of human life, or had it been ever taught in medical institutions systematically or otherwise, as of any value in saving human life. For over eight years prior to my first operation of forced respiration upon a human being I had been a practical vivisectionist in the physiological laboratory, and during that time I never heard it even hinted that a human life might be saved by the laboratory methods.

It was in the field of paralysis of the respiratory centres from opium that I began my work with forced respiration and the demonstrations as to its efficacy, from the first, could not be questioned. Each and every case saved had passed beyond the limit of hope so far as all known and systematically applied methods of resuscitation were concerned. To be denied the credit which should in all fairness be accorded to the practical originator of a method of such far reaching importance in the saving of human life is what I could not quietly submit to. "Honor to whom honor is due."

RÉSUMÉ OF CASES OF FORCED RESPIRATION TO DATE.

Case 1.—Buffalo, N. Y., adult, morph. sulph., 20 grains taken. Artificial respiration and antidotes had failed. Case given up as hopeless. Dilatation of pupils, last stage of asphyxia taken place. Forced respiration for two and one-half hours, with difficulty on account of incomplete apparatus, saved patient.

Case 2.—Prof. Dr. Boehm, Vienna, Austria. Two months later, and after Case 1 had been fully reported

to the Medical Congress at Washington, and published by the public press. Adult. Nearly 8 grains morph. sulph. taken. Artificial respiration failed and forced respiration saved the life of the patient.

In these two cases the methods used in the physiological laboratory were applied.

Case 3.—(Dr. Fell's 2nd Case), adult. Tr. opii. ζ ii taken, all absorbed. Artificial respiration, antidotes, pushed to utmost, but they failed. With my new apparatus adapted to forced respiration on man, this patient was kept alive for fourteen hours before he could breathe for himself, and made a good recovery.

With the laboratory apparatus as used in my first case I could not have saved the patient.

Case 4.—Dr. Fell, Buffalo, N. Y. Adult. Tr. opii. ζ ii, taken. Anterior jugular vein and trachea severed by a razor. Hæmorrhage very profuse, patient almost exsanguinated. A corps of hospital physicians had given up the case. The coroner and undertaker even on hand with a coffin. At 5 o'clock P.M., I began breathing for the patient by forced respiration. 9 P.M., patient first conscious; 4 A.M., case considered hopeless; intravenous injection of salt solution ζ vi; 10 A.M., patient improved. At 1:30 P.M., or twenty-one and one-half hours from the time forced respiration was first instituted, the patient was left for a short time to breathe for himself. Becoming tired he requested the renewal of the forced respiration so that fully one whole day was used in forced respiration before auto respiration was thoroughly reëstablished. This gentleman is now living in good health at Wheeling, W. Va.

A few months after this my third case, these three gentlemen whose lives had been saved by my labors voluntarily appeared at my request before a section of the New York State Medical Association at Buffalo.

Case 5.—Dr. Fell, Buffalo, N. Y. Adult, 80 years of age. Tr. opii. ζ i taken. Forced respiration kept patient alive twelve and one-half hours after he had been given up by a hospital staff.

Case 6.—Dr. Fell, Buffalo, N. Y. Infant only 18 days old. Morph. sulph. 1 gr. given by mistake of a homœopathic physician.

Five hours after this large amount, equivalent to about eighty doses, forced respiration per tracheotomy kept the child alive nearly five hours. The results in this case were startling in the manifestations produced.

Case 7.—Dr. Fell, Buffalo, N. Y. Morphia in large but unknown quantity taken. Operation of tracheotomy undertaken after the pulse at both wrists lost; dilatation of asphyxia had taken place; auscultation failed to detect heart action; blood venous on tracheotomy. Forced respiration produced the return of the pulse at both wrists, and clear action of the heart on auscultation; blood became arterial; heart ceased beating in about one hour.

Case 8.—Dr. Fell, Buffalo, N. Y. Still born infant. Compression of brain prevented forced respiration from proving successful.

Operation suspended before heart ceased beating.

Case 9.—Dr. Fell, Buffalo, N. Y. Adult. Tr. opii, 2 ounces taken. Face mask held life until tracheotomy

made. Eleven hours of forced respiration saved patient.

Case 10.—Dr. Fell, Buffalo, N. Y. Adult. Morphia, 5 grains to 10, and tr. opii, 2 ounces taken. Forced respiration for fourteen hours saved patient.

Case 11.—Dr. Fell, Buffalo, N. Y. Young woman had taken 1 or 2 ounces tr. opii. Forced respiration for four hours with face mask saved patient.

Cases 12, 13, 14.—Dr. C. R. Vanderburgh, Columbus, Ohio. Three cases, face mask used. Forced respiration for two to four hours saved patients.

Case 15.—Dr. Fell, Buffalo, N. Y. Adult female. Morph. sulph. in large quantities taken. Forced respiration for seven hours kept patient alive, where Sylvester's method of artificial respiration in the hands of another physician signally failed to prevent returning cyanosis. Forced respiration with face mask quickly overcome it, but was given up for Faradayism which resulted fatally. Forced respiration would have saved this case.

Case 16.—Hospital case reported as saved by the Fell method. Particulars not obtained.

Case 17.—Dr. Fell, Buffalo, N. Y. Young lady medical student took 15 grains of morphia. Forced respiration with face mask for three hours, and per tracheotomy for about ten saved her life.

During this case auscultation failed to detect heart action and pulse at wrist was absent for a time.

Case 18.—Dr. Fell, Buffalo, N. Y. Adult. Over doses of phenacetin, morphine and cocaine taken accidentally. Forced respiration for eleven hours with the face mask, and per tracheotomy for about seven, failed to save life. Dr. Fell was absent some time before death took place.

Oxygen gas was used in connection with the apparatus with good results in these last two cases.

Case 19.—The value of forced respiration as a tiding-over measure in various conditions was exemplified in the following case. An old lady, seventy-three years of age, had taken, through the carelessness of a druggist, a dose of aqueous solution of corrosive sublimate. It resulted in producing a condition of shock; cyanosis was supervening, and death, which was inevitable, would have soon ensued. Forced respiration with the face mask easily applied, toned up the system so that respiration was much improved, and the patient lived about two days longer for the treatment.

Oxygen gas in this case, probably at too late a period, had no influence on the case.

I have received indefinite reports of cases occurring at other points which I am unable to report at this time. The record is sufficiently full to indicate the wonderful results of the method.

As the necessity has arisen by which the successful methods in forced respiration may be distinguished from those which are obsolete or impracticable and have resulted in casting a ban upon a most valuable operation by which, when properly applied, many human lives may be saved, I suggest that my method be known as the *Fell method of forced respiration*. Briefly it covers the method per tracheotomy, face mask or intubation tube, with the regularly intervalled respiratory movements indicated by the bellows, and controlled by the air valve in the hands of the surgeon; or the use of the bellows and other factors without the intervention of the air valve.

Very respectfully, GEO. E. FELL, M.D.

72 Niagara St., Buffalo, N. Y.

BOOK REVIEWS.

MEDICO-CHIRURGICAL SOCIETY OF GLASGOW. DISCUSSION ON ANÆSTHETICS. Edited by J. WALKER DOWNIE, M.B., F.F.P. and S.G., Secretary. Glasgow; 1891. pp. 136.

This little book is a reprint from the *Glasgow Medical Journal* of a discussion on the subject of Anæsthetics which took place at three successive meetings of the Medico-Chirurgical Society of Glasgow, held respectively October 17, 24 and 31, 1890. There is an introduction by Dr. William Macewen, and papers as follows: "The Action of Anæsthetics on the Respiration and Cardiac Action, and on the Risks Incident to this Action," by Dr. Joseph Coats; "On the Relative Value of the Various Anæsthetics," by Dr. T. Brown Henderson; "Ether as an Anæsthetic," by Dr. Hartley, of Leeds; "On Primary Chloroform Syncope," by Dr. Robert Kirk; "Thirty-five Years Experience of Anæsthetics," by Sir George MacLeod; "Anæsthetics in Relation to Midwifery," by Dr. William L. Reid; "Anæsthetics in Dental Practice," by Dr. Woodburn; "Nitrous Oxide, Cocaine and other Anæsthetics," by Dr. W. J. Fleming; "Causes of Death Under Chloroform," by Dr. Beatson; "On Various Anæsthetics, with Special Reference to Methylene," by Dr. G. A. Turner; "The Chemical Aspects of Anæsthetics," by Dr. George Buchanan; "Experimental Observations and Inferences Relating to the Physiological Action of an Overdose of an Anæsthetic," . . . "Indications of Danger in Chloroform Narcosis," by Dr. David Newman; "The Administrations and Dangers of Anæsthetics," by Dr. James Dunlop; "Special Remarks on Ether," by Mr. H. E. Clark; "Anæsthetics in Diseases of the Heart," by Dr. Alex. Robertson; "Anæsthetics at the Children's Hospital," by Dr. Ness; "Anæsthetics in Practice," by Dr. Walker Downie; "Anæsthetics in Obstetric Practice," by Dr. Samuel Sloan. Besides the formal papers above mentioned, there are brief discussions by Dr. Murdoch Cameron, Dr. Renton, Dr. Hector Cameron, Dr. McConville, Dr. Carmichael, Dr. McGregor Robinson, Dr. Stirton, Dr. Lapraik and the president of the society, Dr. William Macewen. The society has shown a commendable desire to avoid redundancy in both the papers and the discussions, and their conciseness adds to their value. The results of the Hyderabad Commission are sustained, and in conclusion, Dr. Macewen gives the most cogent reasons for his adherence to chloroform, and while he clearly states his preference, is undoubtedly fair to the adherents of ether. He gives a statement of the dangers of ether in its after-results, in which bronchitis and pneumonia are mentioned. He

omits mention of the most serious of all, and that is, the fatal renal congestion that may follow the prolonged use of ether in cases of fatty kidney, or, indeed, in any stage of nephritis. In such conditions ether is, without doubt, wholly contra-indicated. The book as a whole is a worthy companion to the recent report of the Hyderabad Commission and the well-known text book of Prof. Lyman.

J. B. H.

NECROLOGY.

DR. JAMES K. THACHER, of Yale Medical College, died April 21, 1891, aged fifty-four years. He was the eldest son of the late Professor Thomas Thacher of Yale, and a graduate of that university in 1869. Ten years later he took his medical degree from the Medical Institute at New Haven. The interval had been filled by several series of original investigations regarding comparative anatomy and physiology; part of the time being, also, taken up by his duties as a college instructor. The Transactions of the Connecticut Academy of Sciences contained the results of his studies, which attracted the attention of the scientists in all parts of the world. He claimed that the limbs of the higher vertebrates were developed from the fins of fishes, a view sufficiently novel at the time he advanced it, but which has since been strengthened by later investigations. He became Professor of Physiology soon after graduating in 1879, and engaged in general practice. He received an appointment in the New Haven Hospital, and the chair of clinical medicine was added to that of physiology. He was one of the medical editors of the new Century Dictionary.

MISCELLANY.

MITCHELL DISTRICT MEDICAL SOCIETY.—The annual meeting of this Society will be held at West Baden Springs, Thursday and Friday, July 16 and 17, 1891.

Thursday, July 16. Morning session, 10 A.M. Calling Society to order.

1. Welcome to visitors, A. M. Owens, M.D.
 2. Greeting and welcome to visitors from other States, Edwin Walker, M.D., President Indiana State Society.
 3. Response, Kentucky and Ohio.
 4. Report of Society.
 5. Reception of new members.
- Afternoon Session, 2 P.M.
6. "Antiseptic and Aseptic Surgery," J. B. Duncan, M.D., Petersburg, Ind.
 7. "Excision of Varicose Veins," J. T. Freeland, M.D., Bedford, Ind.
 8. "Suicide," T. M. Kyle, M.D., Aurora, Ind.
 9. "Technique in Laparotomy for Diseases of the Tubes and Ovaries," W. H. Wathen, M.D., Louisville, Ky.
 10. "Inflammation," Chas. Knapp, M.D., Evansville.
 11. "Septic Infection of the Newly Born," Geo. T. McCoy, Columbus.
 12. Paper, A. J. McDonald, Bedford, Ind.

13. "Importance of Local Treatment in Scarlatinal Throat Affections," Thomas Hunt Stucky, M.D., Louisville, Ky.

Evening Session, 8 P.M. "Conversacioncz."

Friday, July 17, 8 A.M.

14. "School Hygiene," T. F. Wood, M.D., Wertz, Ind.
 15. "Puerperal Eclampsia," T. S. Galbraith, M.D., Seymour, Ind.
 16. "Antipyretics," E. S. Elder, M.D., Indianapolis.
 17. "Intestinal Obstruction, caused by an Abdominal Tumor with Twisted Pedicle, Laparotomy, Recovery," Thad. A. Reamy, M.D., Cincinnati.
 18. "The Tampon in Rectal Surgery," J. M. Matthews, M.D., Louisville, Ky.
 19. "The Best Method of Treating Fractures of the Femur," A. M. Owens, M.D., Evansville.
 20. "Truss Treatment of Inguinal Hernia," J. W. Marsee, M.D., Indianapolis.
- Afternoon, 1:30 P.M.
21. "Hypertrophic Rhinitis," T. C. Kennedy, M.D., Shelbyville, Ind.
 22. "Management of Office Gynecological Patients," Edwin Walker, M.D., Evansville, Ind.
 23. "Spinal Curvature," J. A. Comings, M.D., Indianapolis.
 24. "Granulated Lids," D. S. Reynolds, M.D., Louisville, Ky.
 25. "New Methods of Treating Tuberculosis," Theo. Potter, M.D., Indianapolis.
 26. "Limitations of Palliative Treatment of Enlarged Prostate," W. N. Wishard, M.D., Indianapolis.
- Volunteer papers and case reports are solicited. The management at West Baden Springs has made a rate of \$1 or \$1.50 per day (according to room) on account of those in attendance at this meeting. Season tickets are on sale at all principal railroad offices. So far as possible, the Society will endeavor to accommodate those presenting papers to suit their convenience. Officers of the Society: President—A. M. Owens, M.D., Evansville; Vice-President—H. W. Shirley, M.D., Shoals; Secretary—Geo. W. Burton, M.D., Mitchell.

THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS will hold its fourth annual meeting at the New York Academy of Medicine, 17 West Forty-third St., in the City of New York, Thursday, Friday and Saturday, September 17, 18 and 19, 1891, under the Presidency of Dr. Adam H. Wright, of Toronto. All physicians interested in the discussion of subjects pertaining to abdominal surgery, obstetrics and gynecology, are invited to attend without further formal notice. By order of the Executive Council.

WILLIAM WARREN POTTER, M.D., Sec'y.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from June 27, 1891, to July 3, 1891.

Asst. Surgeon Edward C. Carter, relieved from duty at Ft. Walla Walla, Washington, and assigned to duty at Ft. Canby, Washington.

Asst. Surgeon C. B. Ewing, U. S. A., is granted leave of absence for one month.

Asst. Surgeon J. O. Skinner, U. S. A., upon the abandonment of Ft. Davis, Tex., will proceed to Ft. Clark, Tex., and there take station.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Three Weeks Ending June 27, 1891.

Surgeon J. B. Hamilton, ordered to Washington, D. C., on special duty. June 9, 1891.

Asst. Surgeon H. D. Geddings, ordered to New York, N. Y., on special duty, June 13, 1891. Ordered to Washington, D. C., on special duty, June 26, 1891.

Asst. Surgeon C. P. Vertenbaker, when relieved at Galveston, Tex., to proceed to Chicago, Ill. for duty. June 23, 1891.

Asst. Surgeon A. C. Smith, relieved from duty at New Orleans, La.; ordered to Galveston, Tex. June 23, 1891.

Asst. Surgeon W. G. Stimpson, ordered to New York, N. Y., for temporary duty. June 12, 1891.

Asst. Surgeon M. J. Rosenau, when relieved at Chicago, Ill., to proceed to New Orleans, La., for duty. June 23, 1891.

ORIGINAL ARTICLES.

THE SCIENTIFIC RATIONALE OF MODERN WOUND TREATMENT.

Read in the Section of Surgery and Anatomy, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 5-8, 1891.

BY HENRY O. MARCY, M.D.,
OF BOSTON, MASS.

The currents and counter-currents of surgical opinion, which dominate the methods of wound treatment, are perhaps nowhere better illustrated than at present in the public hospitals of London. In one of these the great founder of antiseptic surgery explains to his pupils and a very considerable number of surgeons, who gather daily in his wards from all parts of the world, the fundamental principles upon which his methods are formulated. These he exemplifies with painstaking care in the great variety of operations which are done in the amphitheatre of a large general hospital. It is noteworthy to observe that drainage is considered far less important than was earlier taught, although every wound is dressed with ample provision for protection from extraneous contamination, with the expectation that there may be, at least, a certain amount of serous or bloody fluid escaping from the wound, which must be prevented from becoming infected. Mr. Lister now feels certain that the double cyanide gauze is by far the best protective dressing that has yet been devised.

In Guy Hospital carbolic spray may be seen in daily use, as a still further protection during the dressing of wounds, which is usually done at the bedside in the wards. In another hospital all this is openly abandoned, and antiseptics is not only considered useless, but harmful. Here, however, it is noteworthy to observe that the so-called system of cleanliness, which is emphasized, is antiseptic so far as it is possible to destroy the septic material with which, in life, all individuals are usually surrounded and must necessarily come in contact. This pertains especially to the field of operation, the operator, his assistants and the material used by them.

In Birmingham the surgeon, most often heard from in unmeasured terms, scouts all the pro-

cesses pertaining to antiseptic surgery as "illogical and unscientific"; claims that even the vital tissues themselves in a state of health have ever present in them infective material, and that the dominating surgical thought of to-day is already an exploded fallacy, and that the system so elaborately constructed by Professor Lister is "as dead as Julius Cæsar."

In the great hospitals of Berlin there is a singular uniformity of method, revolutionizing all the work of the earlier days, both in technique and results.

In America, where individual opinion has its expression with the greatest degree of freedom, individuality is more noteworthy, and, although the teaching of surgery in the great centers of learning is largely based upon the fundamental principles as elaborated by Sir Joseph Lister, there is too often seen a carelessness of method, especially in detail, and corresponding imperfect result which indicates either a disbelief in or an imperfect knowledge of what, for my own part, I had supposed long since considered demonstrated.

It is wise and ever profitable analytically to review, with critical care, our own convictions and experiences. This is not alone philosophic, but in large measure the way in which advancement may be made, and oftentimes leads to the condemnation and abandonment of our own most cherished ideas, resulting in the adoption of new means by which to reach a given end. Only by such measures can the individual himself become progressive and keep apace with the tide of accumulated observations, with the assimilation of new truths, and himself become an important contributor to the advancement of science.

In this spirit, and not as a partisan, do I purpose to claim the attention of the section to a brief discussion of the scientific rationale of wound treatment, necessarily brief, since it were easier to write a volume than to attempt a correct presentation of the subject in the short time at my disposal.

So omnipresent is the appearance of vital activity in all organic material that we cannot wonder that it long went unchallenged as an inherent factor. The ever illusive search for the beginnings of life led to the belief in a spontaneous generation, under favorable conditions, and to the

solution of this problem we are first of all indebted, as the foundation of subsequent demonstration. Here Pasteur, Tyndall and many others of scarcely less note laid the foundations of a practical science as wide-reaching as humanity, the importance of which hardly dawned upon their perception. In this connection it affords me the greatest pleasure to pay tribute to one of my earliest and most loved teachers, the late Prof. Jeffries Wyman, of Cambridge. In the *American Journal of Science and Arts*, vol. 34, July, 1862, Prof. Wyman gave an account of some experiments on the formation of infusoria in boiled solutions of organic matter, the result of which was that such solutions, exposed only to air which had passed through iron tubes, heated to redness, became the seat of infusorial life; the same results followed when similar solutions were enclosed in hermetically sealed flasks, and subsequently exposed to the action, for a short period, of boiling water. In a few instances, infusoria appeared when the temperature was raised above 212° F.

He says: "All living beings found under the above circumstances have been attributed either, 1st, to organisms, or the germs of them, supposed to be contained in the fluid experimented with, or the air included in the flasks; or 2nd, to the direct transformation of organic matter into new living beings, independently of any germs, or living organisms whatever; or in other words, to 'spontaneous generation.' Abundant proof has been brought forward to show that the spores or germs of infusoria exist in the air in quantities amply sufficient to account for the presence of living organisms in solutions freely exposed."

"There can therefore be no certainty of the existence of spontaneous generation in a given solution, until it can be shown, that this has been freed of all living organisms which it contained at the beginning of the experiment, and kept free of all such from without during the progress of it. On the other hand, this kind of generation becomes probable, whenever it is made certain that infusoria do appear in solutions, in which the conditions just mentioned have been complied with."

For the purpose of determining whether infusoria can develop in organic fluids freed from living organisms which are kept secluded from atmospheric contact, Dr. Wyman entered into a long series of experiments with boiled solutions of organic matter in sealed flasks, which experiments were published in the *American Journal of Science and Arts*, September, 1867. The material used was the albuminoid product, usually boiled and filtered beef juice. The experiments were twenty in number and each usually consisted of a series of flasks, subject to a great variety of exposures. The contents of the flasks were afterward carefully studied by himself and Prof.

Henry J. Clarke, and the different varieties of bacteria were diagrammed, as seen under the microscope, enlarged from two to four thousand diameters. Prof. Wyman arrived at the conclusion, that at the temperature of boiling water, when continued for a sufficient period, the organic solutions contained in the flasks were completely sterilized, and that no matter what the surroundings or conditions, the fluid remained sterile until again brought into contact with the atmosphere. Under recent date, Dr. Morrill Wyman, of Cambridge, brother of the late Professor Jeffries Wyman, wrote me that some of the flasks used in these original experiments still remain with contents free from any evidence of life.

These original researches by one of America's most distinguished investigators are worthy of permanent record in the relation which they bear to antiseptic surgery. It seemed but a logical sequence that the introduction of these low forms of organic life into the albuminoid secretions of wounds would there germinate and be the legitimate cause of subsequent decomposition, producing all the train of evils incident to suppurating wounds.

Having once demonstrated that the cause of decomposition in organic fluids was due to an extraneous something, usually everywhere present, and that *that something* consisted of certain definite forms of life introduced into them from without, these factors were plainly applicable to the treatment of wounds, and in this commenced the monumental labors of Mr. Lister.

The question, naturally, soon broadened out to determine, if possible, the varieties of bacteria which develop within the organism during the life of the higher animals, the peculiar conditions incident to their growth, and if certain varieties were more harmful than others. In other words, it became necessary to study *de novo* certain chapters of natural history, involving several families of the lowest orders of plant life. All this is now recognized as so important that bacteriological researches, from the standpoint of laboratory investigations, are included in the curricula of all the better equipped universities. These additions having been made to science, it naturally followed that, when the conditions of bacterial reproduction were known, it was then, and not *until then*, that the investigations of changed relationships which would limit, restrict, or prevent, their development could be intelligently undertaken.

Many of these investigations have borne fruitage of the greatest value to the human race. We now have the scientific demonstration of this in man, in the easy control of small pox by vaccinia, established by the immortal Jenner, in the lower animals, in the valuable illustration of the same teaching by Pasteur in chicken cholera, and in the more recent and by far more important

original investigations and demonstrations by Dr. Frank Billings, of Nebraska, in the limitation and control of hog cholera.

Very naturally this line of research has been extended, until it may be accepted as demonstrated that the large share of contagious and infectious diseases to which the human race is liable, are due to the introduction within the organism of a variety of spore plant growth, the development of which is the causative agent of the given disease. I need only to refer to the oft-repeated and generally accepted demonstrations of these important truths as illustrated in anthrax, cholera, tuberculosis, pneumonia, diphtheria, typhoid fever, measles, scarlet fever, etc.

Although quite a variety of other forms of growth may be introduced into the human system and germinate to the production of disease and death through the medium of an open wound, as for instance, anthrax, or diphtheria, it was speedily demonstrated that the poisoning of wounds was chiefly due to the micrococcal or round-celled growth. It was shown that these could be isolated, cultivated artificially, that they bred true, and upon reintroduction into wounds they always produced the same general class of symptoms and poisoning. Familiar illustration of this is found in erysipelas.

To show the fallacy that all organized material possesses in itself the means by which decomposition may go on spontaneously, a, so-to-speak, inherent bacterial infection of low order, the early experimental observations of Prof. Wyman already alluded to, then demonstrated that the vital organisms contained in organic fluids were destroyed by the simple process of prolonged boiling, or by a retention for a considerable period at the heat point not above 212° F. A much more simple series of experiments unquestionably show that organic fluids, introduced into sterilized flasks without bacterial contamination, do not undergo decomposition, although freely exposed to atmospheric contact, provided that there is a protection of a slight packing of sterilized cotton which serves to filter out the germs of decomposition commonly present in the atmosphere. This is easily demonstrated in urine or blood exposed to very considerable elevations of temperature, and these highly organized fluids remain sterile, unchanged indefinitely. The exposure of these same fluids to the atmosphere of a common living room, by the simple removal, for a few minutes, of the cotton protective, is sufficient to cause a rapid decomposition to ensue by the development of atmospheric germs coming in contact with them. This is shown to be a fundamental fact, pertaining not only to the fluids of the body, but equally also to the organized tissues, when treated in a manner that shall exclude from the same the extraneous germs of decomposition.

In reply to an able and exhaustive argument

by Professor James L. White, of Philadelphia, upon the present position of antiseptic surgery, Mr. Tait, of Birmingham, publishes in the *British Medical Journal*, February 14, 1891, a defense of his position, from which I am constrained to make an extract, since Mr. Tait is so often quoted as an authority to prove the uselessness of what is called the antiseptic system of wound treatment: "Fortunately for my present purpose, Prof. White puts the issue syllogistically, and formulates for both of us a major premise upon the truth or error of which depends the whole conclusion; and I accept this issue freely. I say that germs of decomposition exist already in the blood and elsewhere in the body and are ever present, but do not bring about their results till death, or some condition which we may call a tendency to death, gives them permission so to do. Professor White says that the elaborate and carefully conducted experiments of Houser, Watson, Cheyne, and others completely contradict the statement 'which is really the foundation of Mr. Tait's argument.' In reply, I say I care not a straw for elaborate and carefully conducted experiments, no matter at whose hands, when their conclusions are diametrically opposed to every day experience." . . . "In truth the facts of the housekeeper and the henwife are far more scientific, that is, far more exact than those of our biological experimenters. They are in harmony with what I see in my work every day and therefore it seems to me a perfect waste of time to follow Professor White beyond his own major premise, which is utterly mistaken."

It may be accepted that the proof of the mistake in the major premise, as based upon such demonstrations, will not be received by the profession, as scientific, or determined, and to me it seems, in large measure, a waste of time to attempt to refute them. Really the housekeeper bases the entire art of preservation of all her organic compounds upon the demonstrations of Professor Wyman, already referred to. Upon these has developed the preservation of the food products, by the canning system in use in the various parts of the world. In America the meats of Texas, the fruits of California, the salmon of Alaska, are familiar illustrations of great economic commercial value in supplying our daily wants, giving employment to thousands of people and furnishing a product of an annual value of millions of dollars.

We might broaden the inquiry to the natural decomposition of fruits and vegetables, including all the grains. Break the epidermal cells of the skin of the grape, the orange, pear, or apple, and all know the rotting of the fruits by the rapid development of a low order of new growths. All the starchy seeds, bulbs, and grains, are protected by an impermeable envelope during their so-called sound state. There is no vital force which

holds in preservation these starch cells, they are simply stored up, like the albuminoid products of the egg, to serve as food in the development of the germinal cells in the earlier stages of reproduction, until the plant has reached a stage of evolution with sufficient inherent power for an independent existence.

If I understand at all what is meant by the demonstration of the henwife, it is simply this and nothing more, that the vitalized ovum is surrounded by a mass of nutritive material, enclosed for its better protection in a porous casement of lime salts, which albuminoid material contained therein is utilized for the development of the growing chick and dominated by vital forces, which elements become parts of a vital organization in precisely the same manner as when the independent individual utilizes its food, which in later life is received into the organism through the alimentary canal. The chief difference that pertains in the characteristics of the growing organism, is that in the oviparous animals the nutriment necessary for the development of the ovum is emitted in a mass sufficient for the purposes of the economy of complete development, while in the mammalian vertebrates the foetal nutrition, by the process of secretion and absorption, is elaborated *pari-passu* to meet the necessities of the growing organism. In the one instance, the egg, when devitalized, speedily undergoes bacterial decomposition, introduced through the protecting envelope from without. In the other, as Mr. Tait should well know, the foetus, having perished within the uterus, undergoes a process of maceration, but never decomposition, unless by the introduction of germs from without. Therefore, it is evident that Mr. Tait's major premise, as he understands it, based upon the scientific deductions of the housekeeper and henwife, are subject to revision, and indeed, when carefully studied, are strictly in accord with the scientific observations, as daily conducted in our better laboratories.

The problem confronting the surgeon is easily subdivided into the two chief factors viewed from the aspect of strict science. The first factor, based upon the accepted premise which I am sure few would have the hardihood to consider "illogical and unscientific," that the vital organism with which surgery has to deal is, itself, in health, free from bacterial ferment, protected from without by a coat of mail, when unbroken impermeable to invasion, and from within through its mucous surfaces by a similar disposition of protective cells, is that all operative wounds made in such tissues should be, as far as possible, made and maintained aseptic; the second, when septic, to determine the best measures for the destruction of the infecting organisms. The wounds of the first class are liable to extraneous infection from everything with which they may come

in contact, and hence the necessity for sterilizing the surroundings and the material applied. It is sufficient for our present purpose to omit reference to the manipulative detail, as to the means to be used to secure this end. I cannot myself doubt, but that the justly discarded and much abused carbolic spray, in the earlier stages of the problem, served as a valuable means in securing good results. Irrigation serves a far better purpose and in the present state of our knowledge cannot safely be dispensed with. A wound in uninfected tissues should be aseptic, as far as possible freed from devitalized structures, carefully approximated, and held at rest. It should be maintained aseptic by the application of suitable dressings.

The second factor of the problem is a much more difficult one. How to treat a wound made in tissues which are already infected, or to best care for a wound which has by accident become the seat of septic ferment, is a subject upon which there is great difference of opinion. Anything like a satisfactory discussion of the problem confronting us demands the careful study of the varying conditions of the individual, the vital, resistant power of the infected organism, as well as the character and amount of the infection itself. The individualistic resistant force is a constantly fluctuating factor, naturally greater in young life and lessening in accordance with age, surroundings, habits, etc. Bacterial growth in dead tissue, under favorable conditions, goes on to the entire decomposition of the material.

When introduced into the living tissues in small quantity, although the heat point and albuminoid products for its food are ever present, the vital, resistant power of the organism may be such that the bacterial ferment will not germinate at all, or in such a limited degree that at the most the disturbing conditions are strictly local and soon disappear. Under favorable circumstances, the resultant suffering and danger are in direct ratio to the amount of the infected material introduced into the organism, and this may be in such quantity as to entirely overcome the resistant power and rapidly cause its destruction. The character of the seed introduced also varies greatly, the reproducing power of some ferments, as anthrax, being such as no matter how small the quantity greatly to endanger the individual. Not seldom the prick of a needle, carrying a minute portion of bacterial infection from a dissection wound, may introduce a virus into certain localities, where its rapid reproduction produces speedy death, while many of the atmospheric germs, common to all localities, reproduce only feebly under the most favorable conditions and soon disappear.

In tracing out the processes which a healthy organism has at its command, it is of intense interest to note the manner in which Nature rallies

her forces for resisting invasion. The profession have long been familiar with the rapid proliferation of cell character which goes on about a wound, and these changes have been more or less carefully studied from the beginnings of surgery. My earliest teacher in medicine, the late George A. Otis, Surgeon of the United States Army, whose monumental labors in the elaboration of the surgical history of the late War of the Rebellion won for him enduring fame, emphasized the observation that the so-called pyogenic membrane in abscesses was in reality protective to the surrounding parts and was not to be interfered with by surgical manipulation.

We now know that the leucocytes, so familiar to all versed in histological study, are endowed with a peculiar physiological power. One of the first processes which we are wont to observe under the name of inflammation, we find consists in a rapid proliferation of the white cells about the point of invasion, encapsuling, as it were, the foreign material. That they do more than this, having the power to surround and destroy, so to speak, under favorable conditions to digest the bacteria is now generally well known, thanks to the observations of Metschnikoff. Although it is quite too early to draw general deductions from these facts and declare that the entire solution of the so-called vital, resisting power of the tissues lies in this power of the leucocytes, there is every reason to believe that this important discovery gives an explanation of satisfactory type to certain of the hitherto unexplained factors in the repair processes of wounds. In the repair of the minor subcutaneous injuries we have familiar illustrations of the part which the leucocytes play in the animal economy. The effused blood is surrounded by them, and the material of the exudate is appropriated for their own development. Minute capillary vessels are formed in the line of these invading cells and the process of clot disappearance and granulation tissue development go on *pari-passu* until the clot has disappeared and new connective tissue restores the part to its former condition.

When a small colony of micrococcal cells have found lodgment, the leucocytes surround and shut in the enemy, until a wall of living granulation cells are formed, forcing it to surrender, and a localised abscess is the sum total of damage.

If we find in these familiar leucocytes the so-called phagocytes of Metschnikoff, empowered to a certain extent with the ability actually to destroy infecting bacteria, we certainly have in a very considerable measure an explanation of the vital resisting power of the individual organism. If, under favorable circumstances, these cannibalistic little workmen, not alone surround, but actually eat up, their enemies, we have the best of reasons for understanding why the comparatively

few germs in the atmosphere of an healthy locality are far less dangerous to wounds than was earlier supposed.

Again we understand why in the so-called surgically clean wound, a wound where great care is taken to exclude foreign material, and the comparatively uninjured clean-cut surfaces are closely approximated, the reparative processes go on steadily, and rapid recovery supervenes, although in a strictly scientific sense, the wound may not be aseptic. The infected organism suffers in a two-fold manner. First, locally, that is, in the wounded surface and its immediate neighborhood, and in a general constitutional poisoning. The latter is produced by a chemical substance capable of isolation, called sepsin. This may in itself be sufficient to cause death, and its importance can hardly be overestimated, but since it is the direct result of microörganic development, it follows that the control, or destruction, of the organic ferments is the sure way of cutting off the septic, systemic suffering.

In this process, the methods which have been emphasized as aseptic, or surgical cleanliness as in contra-distinction to antiseptis, bear no part except so far as they may aid in removing the products of decomposition. The prerequisite knowledge in this instance must be sufficient to enable the best trained surgeon to make use of those agents best fitted to destroy the organisms in loco with the least possible injury. Hence the wide field of research of a most painstaking and scientific character which must of necessity be traversed before a satisfactory solution of this question could be given. Now, we have the fruitage of a multitude of patient investigators; notably Mr. Lister and Mr. Cheyne, of England, Pasteur in France, Koch in Germany, Sternberg, Cabot and others in America. My own publications upon this subject were the fruitage of two years of carefully conducted laboratory experiments.

The mercuric-bichloride solutions are usually greatly to be preferred as more effective as a destroyer of infection and less irritant to the wounded surface. All pockets in suppurating wounds must be carefully cleansed and drained, while in iodoform we fortunately have an agent, the crystals of which are only in a minor degree irritant, and as such absolutely non-poisonous. They dissolve very slowly and are germicidal only in solution. Hence by their use bacterial development is greatly retarded, if not altogether prevented. The iodoform crystals in most wound secretions, as ordinarily observed, dissolve so slowly that the antiseptic power is continued as a constant factor for hours, sometimes even for days together.

From this hasty, and necessarily imperfect, review of a subject second to none in interest or importance to our entire profession, we have

omitted of necessity very much of value. However, I am certain that "the better methods of wound treatment have a fundamental basis of a strictly scientific character, the three important factors of which are: *First*, the vital resistant power of the individual. *Second*, the character and amount of the bacterial infection. *Third*, the local condition of the tissues at the seat of implantation."

The ideal treatment of wounds is certainly the restoration of the condition of the parts operated upon to, as nearly as possible, their primal state. If this can be effected aseptically, then there are no bacteria to be removed, and if the wound is surgically clean, with accurate coaptation of the sundered parts, then the vital forces are sufficient to utilize any resultant exudates, and drainage is not alone superfluous, but harmful. The reparative process should go on under a dressing which will permit of the introduction of no foreign factorage. The various antiseptic dressings now so generally used, have a value in wounds necessarily drained, that is subject to a probable infection, but in aseptic wounds primarily closed, they are unnecessary, expensive and cumbersome."

For quite twenty years I have been in the constant practice of closing *aseptic* wounds by lines of buried animal sutures. Little by little I have been led to discard drainage, almost without exception, in this entire class of wounds, until I have formulated it as a rule of practice, that no matter how large or deep in non-infected structures, the sundered parts are rejoined, oftentimes by the use of several feet of tendon suture, and the wound is sealed by a germ-proof dressing of collodion. To this rule the larger amputations are no exception, and such wounds thus treated rapidly heal without pain or oedema of the coapted tissues. In reality, it makes little difference by what name we call this modern miracle of surgical wonder-working. It has its establishment upon the foundations of pure science, its future gives promise of still greater achievement, and we may look forward with confident expectancy to the day when medicine and science, although they cannot be exact sciences, will be understood and practiced with a scientific rationale above contradiction or reproach.

My brethren of a noble profession, second not even to that of the clergy, may I not be pardoned a digression? We have spent the last two days in the Councils of the Academy of Medicine intent upon the purpose of elevating the profession to a higher standard of education, comparing the advantages of a general, with those of a technical training. May we not accept that they both should be broadened in the Catholicity of science which is after all the demonstration of God's own law of pure and simple truth? The one profession reads it in the Divine revelation

transmitted through the Fathers; the other is the unerring law of vital forces transmitted from the beginning of creation. The one teaches a mediatorial redemption from the transgressions of the moral law; the other knows of no high-road cast up for the escape from the penalties attached to the infraction of its inflexible government.

Since both emanate from a common source and center of Being, should they not be at least equally respected, investigated and obeyed? He who studies the infinitely minute, and yet sees through it all the marvelous working of a vital law, intended primarily for the beneficent good of the created, is moved by the same divine inspiration as he who measures the infinities of space and weighs the distant stars in balances of mathematical correctness. If I read aright the doctrines of our great republic in the evolution of our race, the time is not far distant when the necessity of sending our young men to the great centres of European thought for a higher development in the training and knowledge of the exact sciences will have passed.

Let our own central government not alone foster the education of the masses as a bulwark of defence in the protection of our own inherent safety, but let her also provide national laboratories which shall amplify the advantages of the Carnegie and John Hopkins institutions for biological researches, the advantages of which to our entire race can hardly be overestimated.

EMBOLISM OF A BRANCH OF THE PULMONARY ARTERY. PATIENT SUSTAINED BY OXYGEN GAS. RECOVERY.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D.C., May, 1891.

BY GEO. E. FELL, M.D., F.R.M., Sy.,

LATE PRESIDENT AMERICAN SOCIETY MICROSCOPISTS, PROF. PHYSIOLOGY AND MICROSCOPY MED. DEPT., NIAGARA UNIVERSITY, BUFFALO, N. Y.

One of the remarkable conditions associated with the blood vascular system is, that with all the radiations of the capillary system, we have so little disturbance in the blocking of these minute channels. It is true that without some external influence acting on the coats of the vessel, or some modification of the blood, or walls of the vessels through and by which the fibrin factors are disturbed in their normal relations, we could not readily ascribe a cause for the accumulation of any substance which would block or disturb the activity of the circulation. We do, however, have modifications of the blood, as in albuminuria, which appears to permit such abnormal changes to exist, so that the fibrin-forming factors take on an abnormal state, with the conse-

quence of the formation of a greater or less amount of fibrin, resulting in a clot. The size of this clot, of course, has a very great bearing upon the prognosis in these conditions. In the pregnant state, with albuminuria preceding labor, we have just such a condition existing whereby the excessive strain upon the uterine vessel, and the more or less mechanical effect produced by the passage of the fœtus, we may have the vessel so disturbed that a clot may readily form. The history of the subject gives us the authority to state, that emboli do form, and frequently to a very great extent, so that the functions of important vessels in various parts of the organism are interfered with, thus disturbing to a greater or less degree the physiological relations of the parts affected. It may be stated in passing, that clots of so large a size have been formed that on entering the right side of the heart they have immediately disturbed the function of this organ so as to produce immediate death.

When the embolus passes into the pulmonary artery so as to completely occlude this important vessel, of course death must immediately ensue. However, we may have many conditions existing wherein only portions of the vascular area, to which this important vessel is distributed, are disturbed, and I now have the pleasure of being able to report a case in which all the evidences point to such a condition. Before, however, entering upon the details of this case, we will refer briefly to the results of emboli forming in various parts of the body. The result of the occlusion of a small artery is simply told in the following words, modified from Coles' Histology.

"In embolism a small mass of coagulated blood or fibrin, a small mass of tissue separated from an organ by ulceration (endarteritic modifications), some extraneous matter penetrating into the vessels in some way or other and carried away by the blood stream, on reaching the small branches of the arterial system, become impacted and suddenly interrupt circulation for a time in the area supplied by the vessel plugged. In the same manner thrombosis and the addition of coagulum products would cause more or less complete anæmia of the area supplied by the obliterated vessels. The effects of the occlusion of arteries which do not freely anastomose with other arteries of the same size, so-called terminal arteries, are simple to understand if we keep in mind the way in which blood circulates through an organ thus supplied. The blood passes from an artery into smaller arteries, and finally into arterioles. These arterioles end in a plexus of capillaries (or in the lungs in the wonderfully minute ramifications in the air vesicles). From these capillaries veins corresponding with the arteries originate, but although a terminal artery does not anastomose with other arteries, the capillary plexus belonging to it is continuous with

the capillary plexus corresponding to neighboring arteries. "When one of these arteries is obstructed from some cause or other, the first effect is the stoppage of the flow of blood through all its branches, and in the lungs, consequently, a less area of respiratory surface is produced." The blood remains nearly stagnant in all the area supplied, except at the periphery where the capillaries join to adjacent arterial systems. A very slight amount of blood penetrating through these collateral vessels into the stagnant area; blood still passes very slowly from it into the corresponding vein, but the circulation is so sluggish that the walls of the vessels lose their vitality by degrees, and consequently their tone. They become more or less distended, and in this stage the infarct may assume the appearance of a hæmorrhagic block. However, stagnation is soon followed by coagulation and complete arrest of blood flow, and in organs like the kidneys, liver, brain or spleen, the tissues and the blood itself degenerate as the functional and organic circulation are associated in the same vessels. "In the lungs, however, owing to the bronchial vessels supplying nutrition, there is less tendency to necrotic changes. In the former organs the blood becomes granular and discolored." At the periphery of the infarct other phenomena take place. They are due partly to the increased blood pressure in the collateral vessels resulting from the increased supply caused by the obliteration of one of the channels through which the blood had to pass, and partly (and probably chiefly), to the modified and sluggish state of the circulation in the capillary zone common to the system of the obliterated artery and that of the neighboring arteries. In that zone of sluggish circulation leucocytes accumulate in the vessels, diapedesis takes place and causes infiltration of the tissue. Small hæmorrhages are very common, and the tissues are in a low inflammatory state. It is evident that part of this zone belongs to the area supplied by the occluded artery; and in sections of hæmorrhagic infarcts it is easy to demonstrate that this zone is supplied by the collateral capillary circulation."

This description of the action of an embolus refers to the kidney structure, and it will apply equally well to similar conditions existing in branches of the pulmonary artery. In the latter case we have the circulation cut off to a greater or less extent from the air vesicles supplied by the occluded artery and its branches, thus disturbing, according to the extent of area affected, respiration to a greater or less degree. If the blood cannot pass through the air vesicles of a sufficiently large area, dyspnoea is at once produced. In addition to this, owing to a lessened area of respiratory surface, cyanosis may ensue also to a greater or less extent. It is of course easy to imagine conditions in which the area of

disturbed respiratory surface is so small that the respiratory function is not interfered with to such a degree as to be inimical to life. The grade of disturbance, as stated, may vary between that condition which produces sudden death, and that which produces but a temporary disturbance to the system. In the latter case we may imagine the infarct to have been small in extent, and the changes taking place in it being of such a character that it is absorbed, thus doing away with any serious results supervening through its presence. However, the case which I will relate to you to-day, was of a very serious nature, and only through the happy thought of supplying the patient with oxygen was the decreased respiratory surface enabled to supply sufficient oxygen to the blood to retain the vitality of the system. The value of the treatment cannot be gainsaid. Had oxygen not been used, the result would have been fatal within a very short time, and another case would have been added as the result of embolism following child-birth. How many cases which have occurred in the past might have been saved by the prompt administration of oxygen, of course cannot be surmised, but its evident value was so clearly marked in this instance that it will always be one of the important agents to be recommended in similar cases. Where cyanosis exists oxygen should always be supplied either through the administration of the pure atmosphere, as in cases of paralysis of the respiratory centers, or in cases where the amount of oxygen passed to the lungs is diminished in quantity. An instance of the latter was furnished in a case of membranous croup which occurred with a patient of Dr. Dorr, on Fillmore avenue, this city, in which I suggested oxygen. In this instance, while we did not have a decreased area of respiratory surface, we had a diminished amount of oxygen supplied through the plug of mucus, or membrane, in the trachea. The oxygen administered made up for the loss of air passing into the lungs, and I believe Dr. Dorr will bear me out in stating that his patient's life was saved by the excess of oxygen administered over that ordinarily present in the atmosphere.

In the case of embolism, we had a decreased respiratory surface, and through the supply of oxygen we were enabled to permit this decreased surface to supply sufficient oxygen to keep up the life of the system.¹

Friday, March 3, 1891, about 2 P.M., while engaged in my office work, I was called hurriedly to attend Mrs. J., a sister of an intimate friend, and was informed that Dr. R. L. Banta, the attending physician, desired me to consult with him. I was informed by the brother and hus-

band of the lady that it was a serious case, and accordingly turned my patients out of my office, and hurried to the residence of the patient. On arriving at the house I found the patient in a hazardous condition; dyspnoea very great; cyanosis marked. Dr. Banta, however, was not present. I asked for him, and was informed that he would return in an hour or two. Seeing that the case was one calling for prompt action, and making a diagnosis at once, I sent my carriage with a prescription for oxygen gas, and made no attempt to relieve the patient; as little seemed to offer that could be of service. Within a short time a 40-gallon cylinder of oxygen arrived, and I immediately administered oxygen to the patient. The result was most satisfactory. The relief was immediate so far as the cyanosis was concerned. Dyspnoea, however, continued; rapid heart action and respiration, indicating a diminished area of lung tissue in condition for respiration. From subsequent conversation with the patient, the location and the cause of the trouble were defined. She said: "I could put my finger right on the spot where the trouble existed." Following this the area of the disturbance increased so that a greater portion of lung tissue was involved, and the patient was unable for one or two days after to specify the particular point of disturbance, that is, so far as consciousness would permit. More oxygen was procured. A 100-gallon cylinder was obtained, and about 5 P.M., some three hours after my arrival, it was found necessary to use this, the first cylinder having been depleted. The very short time which elapsed in changing the inhaling apparatus from one cylinder to the other, was sufficient to produce general cyanosis, and I hazard the opinion that at this time the patient would not have lived 30 minutes without oxygen. If in one minute deep cyanosis was produced, I think we have reason to believe that death would have ensued in thirty.

While changing this cylinder Dr. Banta appeared upon the scene, and I found by this time that he had not called me in consultation. He showed considerable surprise at my presence, and deemed himself unjustly treated, not having been notified in fact that a consultation was called. Upon explanation, however, that only on being informed that as physician in charge he had called me in consultation, was I present. To obtain my presence I had been deliberately misinformed. He very graciously accepted the situation existing, approved of the use of oxygen, and together we endeavored to make the best of it, both remaining at the house of the patient through the entire afternoon and night. At no time Friday night or Saturday morning could the patient be left without the oxygen without great discomfort immediately ensuing. Through Saturday the condition remained nearly the same, although with a gradual improvement. Every hour's

¹ Five or six physicians who saw the case in the first 48 hours gave a fatal prognosis, with which the author agreed until the wonderful effects of the oxygen gas and subsequent treatment changed his views.

duration of the case gave us reason to hope that what had been prognosticated by five or six physicians in the first few days as a fatal case, might yet possibly result in recovery. Through Saturday night the case progressed favorably, the gradual improvement continuing so that the patient was enabled to breathe for some little time together without the aid of oxygen. Sunday the area of disturbance of lung tissue was increased to its greatest extent, and Sunday afternoon and night the improvement was evident, although the rapidity of the pulse and respirations kept up, so that it appeared the system would be unable to resist the great strain to which it was being subjected. Sunday night, however, the improvement continued, and Monday morning the patient presented a condition calling for an uncertain prognosis, but yet, as life had existed so long, there was reason to hope that changes might ensue in the infarct which would permit the lungs to resume their normal relation. The area of disturbance included, in its greatest extent, probably about one-third to two-thirds of the whole area of the respiratory surface of the right lung. This was indicated by a slightly oedematous condition of the lung tissue. At no time was the disturbance marked in the left lung, the respiratory murmur being distinct throughout its entire area.

Some strong points in evidence of embolism in this case, were the defined circumscribed disturbance at the beginning of the trouble, the increased area of disturbance gradually following the occlusion of the branch of the artery; the rapidity of the heart action, and of respiratory action,—the former ranging from 170, the first day of the condition, to 150, 140 and 130, upon the third and fourth days,—the respiratory action remaining during the occlusion of the area of respiration of the right lung, at about 50 for several days, decreasing to 40, and then gradually coming down to 30, 24, and to nearly the normal respiratory action about one week following the onset of the trouble.

The patient during the first week of illness was unable to lie upon her left side, or upon the back, with any degree of comfort. The first four days the slightest attempt to lie upon the back, or the left side, was followed by immediate dyspnoea—all these conditions indicating the correctness of the diagnosis, and precluding any favorable argument in support of a purely nervous disturbance, as has been suggested by one of the physicians only who was present during this interesting case.

The lacteal secretion, the locheal discharge, and many of the conditions, or features, following ordinary childbirth, were absent during the five days following the confinement. Albuminuria existed to a greater or less degree for a fortnight following confinement. The absence of

the locheal discharge was considered of so serious a nature that steps were taken to irrigate the uterus. These measures resulted in establishing the flow, and benefited the patient to a great extent. As stated, the patient was unable to lie upon any other than the right side, or upon the back. The irrigation of the uterus was therefore an interesting problem, and the method which I have long used and first reported to the Buffalo Obstetrical Club and which was published in the Transactions of the New York State Medical Association, Vol. 6, 1889, the latero-dorsal (not Sim's position) came into play in a remarkably interesting manner.

The patient was placed on the left side of the bed, lying upon her right side in the Sim's position. The speculum was introduced, and the irrigating tube passed into the womb. The knees were then raised as described in my article, thus permitting the outflow to pass into receptacle provided for it, and the womb was thoroughly irrigated, with the result that immediately the patient was improved, and in two days the locheal discharge was presenting in its characteristic manner. At this time, as stated, no milk was present. On using the breast pump, applied with Allen's surgical pump, and considerable vacuum, a serous discharge, very small in amount, would pass from the nipples. This treatment was kept up day after day, and followed by mild faradization; and within a few days the glands were secreting milk; and within a fortnight from the time of confinement, the mother had the satisfaction of being able to nurse her offspring.

I am glad to be enabled to report a case of this kind, and one which may have a far-reaching influence, resulting in the saving, possibly, of many mothers whose lives might be sacrificed were it not known that in oxygen gas we have an agent which will tide over often, as it did in this case, conditions which would prove fatal without it.

On the Monday following confinement, three days after I first saw this case, a Dr. E. was called, and suggested the addition of nitrous oxide, with what may be looked upon as favorable results. However, I do not consider it probable that the patient, who had been kept alive more than three days with the oxygen, and had used about 1200 gallons of the gas, would have made any the less a good recovery had the nitrogen not been introduced. This physician also stated that the patient was being burnt up by oxygen, but as her temperature at no time was above 99° F. there could be no grounds for such a statement, and the lady's recovery can alone be ascribed to the use of oxygen gas and the treatment instituted to overcome the albuminuria.

Among working men venereal disease is rare in Paris. Thus a late examination of about twenty-five hundred railroad employes showed but three cases of such disease.

TREATMENT OF POSTERIOR FACE PRESENTATION.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, at Washington, D. C., May, 1891.

BY EUGENE P. BERNARDY, M.D.,
OF PHILADELPHIA, PA.

Face presentations are rare, and as a result their mechanism and treatment are not always set out clearly by the different writers.

Dr. A. Charpentier gives the following statistics of face presentations:

Mme. Lachapelle, in 15,779 labors,	72 times.
P. Daboïs	" 2,022 " 11 "
Braun	" 7,835 " 44 "
At Wurzburg	" 8,514 " 58 "
At Gotteugen	" 7,104 " 29 "
Depaul	" 16,233 " 33 "
Pinard	" 81,711 " 330 "

Total	139,198	577
Average, 1 in 241.		

Churchill's statistics for face presentation for British, French and German practice are as follows:

British practice:

Dr. Jos. Clark . . . in 10,387 labors,	44 times.
Dr. Merriman . . .	" 2,947 " 10 "
Dr. Granville . . .	" 640 " 1 "
Dr. S. Cussack . . .	" 701 " 3 "
Dr. Mansell	" 839 " 7 "
Dr. Thos. Beatty . .	" 1,184 " 4 "
Dr. Collins	" 16,414 " 3 "
Mr. Gregory	" 691 " 2 "
Dr. Reid	" 3,250 " 15 "
Mr. Lever	" 4,666 " 24 "

Total	41,719	143
Average, 1 in 291 $\frac{2}{3}$.		

French practice:

Mad. Boivin . . . in 20,517 labors,	74 times.
Mad. Lachapelle . .	" 15,652 " 65 "
M. Ramboux . . .	" 491 " 3 "
M. Daboïs	" 10,742 " 30 "

Total	47,402	172
Average, 1 in 275 $\frac{1}{2}$.		

German practice:

M. M. Moschner and Knrsak . . . in 12,329 labors,	122 times.
Dr. Carus	" 2,557 " 24 "
Dr. A. E. V. Siebold . .	" 1,003 " 10 "
Dr. E. E. V.	" 494 " 4 "
Dr. Kilian	" 9,392 " 122 "
Dr. Merrem	" 157 " 1 "
Dr. Naegele	" 115 " 4 "
Dr. Klugé	" 799 " 6 "
Dr. Brunetté	" 100 " 2 "
Dr. Ademan	" 57 " 1 "
Dr. Jansen	" 13,365 " 15 "

Total	40,765	311
Average, 1 in 129 $\frac{2}{3}$.		

It would seem strange that the larger percentage of cases occur in German practice, excelling in number those of the British and French, but why it should be so is unaccountable.

Charpentier's statistics give 577 face presenta-

tions in 139,198 confinements, or 1 in 241 cases.

Churchill's statistics give 626 face presentation in 129,489, or one in 206 $\frac{3}{4}$. The statistics together give us 1,203 face presentations in 268,677 labors, or 1 in 223 and a fraction of cases.

The causes of this form of presentation are as numerous as are the opinions of the different authors and writers, the obliquity of the uterus predominating as one of the essential causes. Deventer makes the following statement: If the uterus be inclined to the right side and the head or vertex be in the left occipito-iliac position, the uterine contractions taking place in the direction of the uterine axis after the membranes are ruptured, will force the fœtus from above downwards and from right to left, so that the vertex will strike against the left border of the superior strait; the head, thus arrested, will be thrown back upon the posterior plane of the child.

Baudelocque, while admitting the right uterine obliquity, believes that at the same time a right occipito-iliac position of the vertex exists.

Dr. Charles D. Meigs, the first American writer that seems to have thoroughly understood and described face presentations, writes, "The cause of face presentation is not perfectly well understood; it is, however, probable that they are more commonly occasioned by an obliquity of the womb than by any other cause."

Leishman says: "The causes which lead to this unusual occurrence are not well understood, but the initiary movement which results in the position, can only be, as is obvious, a movement of extension, which at an early stage of labor, or prior to its occurrence, is substituted for the usual movement of flexion occurring during labor in the ordinary positions of the cephalic extremity; in other words, and to take the most simple view of the matter, cranial are converted into facial positions by a simple movement of the head on its transverse axis.

It will be seen with what doubt the above theory is advanced. Be the cause or causes what they may, either simple or complex, the fact remains that we have to deal with a premature extension of the head.

It is remarkable what diversity of opinion different writers have, in regard to the mechanism and treatment of this class of presentation. Many simply state that face presentations have the same mechanism as the vertex, the diameters are of the same dimensions and therefore must go through the pelvis in the ordinary manner of a vertex, an undoubted error. Other writers look upon a face presentation as unnatural labor demanding prompt interference. One author dismisses the subject in just 4 $\frac{1}{2}$ lines.

In 1876, Prof. R. A. F. Penrose¹, of the Medical

¹ Penrose on the Treatment of face presentations. American Supplement to the Obstetrical Journal of Great Britain and Ireland. April, 1876.

Department of the University of Pennsylvania, was the first to accurately describe the mechanism and treatment of this form of presentation.

When we compare the mechanism of vertex and face presentation, apparently it will seem that there is no difference, but in reality a great difference exists. In vertex we have the body of the child completely flexed, the chin well thrown on the chest and the head, consequently, in the most desirable position to enter the superior strait; the full force of the contractions is received through the spinal column of the child in practically a direct line to the flexed vertex, the head reaching the floor of the pelvis, the necessary resisting force is encountered, and rotation takes place, the head passing under the arch of the pubis. Face presentations are much more difficult and much more dangerous presentations. In face presentation we have a state of extension, the chin leaving the chest and the head thrown back on the posterior plane of the child; the parturient or propelling forces, instead of passing through the spinal column of the child in a direct line, pass at a right angle; what is the result? The face instead of advancing steadily like in a vertex presentation, advances slowly and uncertainly, descends only as far as the length of the child's neck, one and a half inches, and to advance any farther, it must do so by dragging down the trunk aided by the misapplied parturient forces, increase extension to its utmost limit, we have a jamming of the presenting part, should the chin rotate anteriorly labor may eventually take place. If the chin remain presenting posteriorly, the completion of labor becomes impossible.

O B—Occipito bregmatic diam., $3\frac{1}{2}$ in. T B—Trachelo bregmatic diam., $3\frac{1}{2}$ in. D S—Dorso-sternal diam., 3 in. O D—Occipito bregmatic diam., $3\frac{1}{2}$ in., $6\frac{1}{2}$ in.

All things equal, that is, where there exists a normal relation of diameters of the pelvis and head, my experience has been that if the chin presents posteriorly (either to the right or left) at the commencement of labor and engages

in the superior strait as such, unless changed by manual interference, there remains a posterior position throughout labor.

It will be remembered that the parturient forces are sent through the spinal column in a broken line, at right angle. If, as the picture below will show, the driving force is met by the unequal resistance of the two arms of the face lever. A. F., being the long lever or arm, offers more resistance than A. M., the short lever or arm, the result is, the chin descends and the forehead ascends.

Attitude of the head in face presentation. (Ribémont.)

When the chin is in this position, the neck is put on its extreme tension, the extension increased to its utmost limit, it is compelled to sweep down the sacrum and coccyx, a distance of fully five inches, over the length of the perineum, which is about three inches, making in all a distance to be traversed by the chin, of eight, if not more inches, the child's neck is only one and a half inches in length, therefore before the chin can slide down the sacrum and off the anterior edge of the distended perineum, the child's thorax must be pulled and jammed down into the cavity along with the presenting face. If we study Picture No. 1, it will be seen that we have here presented, the occipito-bregmatic diameter, which is $3\frac{1}{2}$ inches, with the dorso-sternal diameter of 3 inches, making together $6\frac{1}{2}$ inches, to go through a diameter of 4 to the utmost $4\frac{1}{2}$ inches, a radical impossibility.

In anterior face presentation, the chin, by passing under the arch of the pubis, the entire

head can be born before any part of the thorax of the child begins to enter the cavity, but no such act occurs in a posterior face; here the forehead appears first under the arch of the pubis, not acting as a pivot but firmly jammed against it. The first to escape is the chin, then the mouth, nose and eyes, top of the forehead, crown, and at last the vertex, as it will be seen, a mechanism diametrically opposed to an anterior-mento-position.

Anterior face presentation.

Posterior face presentation.

The treatment of mento-posterior positions practically resolves itself into two methods, version and craniotomy.

Several other methods have been suggested, prominent among which is Schatz's method. It is supposed to do away with the introduction of the hands or instruments in the maternal parts. It consists in restoring the normal attitude of the child's body by flexing the trunk and leaving the head to resume spontaneously its proper position as it sinks into the pelvis. The shoulder and breast are seized by the hand and pressed backward, at the same time the breech is raised with the disengaged hand applied near the fundus, making the long axis of the child conform to that of the uterus; then, finally, press the breech directly downward. As the child is raised, the occiput is allowed to descend, then as the body is bent forward, flexion of the head occurs by the

resistance of the side walls of the pelvis. This method is fraught with the danger of the head flexion only partially occurring, leaving a brow presentation in its stead.

In regard to the use of the vectis, I have invariably failed to obtain any good results. Prof. R. A. F. Penrose,² who strongly advocates its use in mento-anterior positions, says: "In mento-anterior position the treatment I have described (vectis or blade of forceps to be applied to the posterior cheek of the child, rotation allowed to occur of itself, not forced) should be resorted to. If, however, the chin be turned to the posterior part of the pelvis (mento-posterior position), we have one of the gravest cases in obstetric surgery to deal with. Anterior rotation of the chin under these circumstances is possible, but so exceedingly improbable, that we have no right to expect it and we should, as soon as the difficulty is recognized, treat the case as one of impossible labor."

Posterior face presentation. (Hodge.)

As to the forceps, they should never be applied when the chin is to the sacrum, it is invariably followed by serious injuries to the mother without due compensation.

While I consider version as the main treatment in this class of presentation, a treatment which rebounds to the benefit of the mother and child, I would urge the greatest discrimination. It should only be performed before the presenting face has passed out of the mouth of the uterus; after the face has entered the pelvis all attempts at version I consider unjustifiable, for version performed under the circumstances has been known to cause laceration of the uterus and other injuries to the maternal passages. Should all attempts fail to produce a favorable change in the presenting face, craniotomy should be performed, not after hours of ineffectual labor, when the mother's

tissues are sodden and their vitality destroyed by the continuous pressure of an impacted face, she herself thoroughly exhausted, but should be done at once. The child's viability is destroyed, though alive, is practically dead, and it devolves upon us to deliver the unfortunate woman as safely and quickly as possible.

The two following cases are taken from my note book: January, 1872, I was requested by a brother physician, (who had broken his forceps in attempting to deliver a patient) to bring my craniotomy instruments. On my arrival I found the patient had been in labor since the previous Wednesday; the day of my call was Saturday. She had been at first in the care of a mid-wife, who had allowed the patient to remain in labor from Wednesday to Saturday; the family, seeing no termination, in spite of the repeated assurance of the mid wife that everything was all right, insisted upon a physician being called. The physician, having diagnosed a posterior position of the chin, attempted to deliver with the forceps, which resulted in a broken pair of instruments. On examination, I found the chin just engaging in the superior strait, free from the mouth of the uterus, presenting in the left oblique diameter, posteriorly. I attempted to force an anterior rotation, the woman's pains being good, I held the face in the anterior-mento for fully half an hour; believing the position permanent, I withdrew my hand, examination a few moments later, revealed the chin in its original posterior position. I then used one blade of the forceps as a vectis, applying it against the posterior cheek of the child, but with no results. Craniotomy was performed and the patient delivered within twenty minutes.

In August, 1885, I was called to assist a brother physician in a case. The patient had been in labor since the previous evening. Examination revealed a posterior chin presentation, not yet out of the mouth of the uterus and just about engaging. The medical attendant, prior to my arrival, had attempted to produce an anterior rotation of the chin without avail. By the time I arrived at the bedside, the patient was exhausted and incessantly crying to be relieved. I determined to perform version at once; ether was administered and within ten minutes a living child was born. Mother and child did well.

It will be seen that in neither case had the chin or presenting part entered the cavity—that has been my experience. Mento-posterior presentations of the chin do not enter deeply into the pelvic cavity, on account of presenting at the superior strait larger diameters than could pass through any of the diameters of the strait.

221 S. 17th St., Philadelphia.

MINOR UTERINE SURGERY.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 1891.

BY J. M. BALDY, M.D.,

PROFESSOR OF GYNECOLOGY IN THE PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE.

In these days of major uterine and pelvic surgery, the minor operations on the uterus, of which we used to hear so much, have been in great measure lost sight of by students of the diseases of women. In consequence of this very fact of being overshadowed by newer and more alluring procedures, fortunately many of the abuses of the old days have disappeared from the practice of those working in gynecology in our large medical centers. Unfortunately this is not equally true of the vast majority of practitioners either in the cities or in the rural districts; the old teachings and the old books still manifest too much influence. The time has come when we should carefully look back over our work of the past few years and see what lessons it has taught us.

The one great fact which stands staring us in the face in this connection, is that most of the troubles which we have been in the habit of considering as situated in the uterus, are not in that organ at all. Thus with one sweep we are able to dispose of a large proportion of the so-called uterine diseases. It is then manifestly improper and dangerous to direct treatment to the uterus, when that organ is perfectly healthy and the trouble is situated in the neighboring tissues—most probably of an inflammatory nature. In a large proportion of the remaining so-called uterine diseases the womb itself is undoubtedly affected, but the lesion in the uterus is only secondary to a lesion in the uterine appendages, or if it was the seat of the primary disease, its continuance is surely due to the inflammatory condition of the contiguous organs. Here again, a treatment directed against the uterus itself is both irrational and dangerous. This leaves us but a comparatively small number of cases of pure uterine disease; such is the true situation. Uterine disease, such as metritis, endometritis, pathological displacements, etc., uncomplicated by other and more serious troubles, is the exception rather than the rule, and in a large dispensary practice during the past few years the small number of such cases which have come under observation, has been a matter of surprise to me.

It would seem, then, that the old methods proposed for the treatment of uterine diseases were not in themselves necessarily faulty, although most of them have undoubtedly been carried to excess, but that the trouble lay in faulty diagnosis and consequent application of methods of treatment unsuitable for the true disease. If the true lesion be overlooked and many of the

* Penrose on Face Presentations.

minor operations be performed, the result is sure to be disastrous in a certain proportion of cases. How often an acute pelvic inflammation will be lit up, will depend, in great part, on how carefully the given manipulation is carried out.

All this being true, there still remain a certain proportion of diseases, which are uterine pure and simple. The fact, that in the past so many mistakes in diagnosis have been made, and that disastrous results have followed the application of certain treatments, should not blind us to the value of these same methods in cases in which they are properly applicable; and yet at the same time a proper limit should be put to their use.

The Uterine Sound.—On the whole it had been better for womankind had this instrument never been invented. For the application of the electric current it has its uses, and in an occasional case where one is uncertain as to the connection of the uterus with a given tumor, it may possibly give some definite information. For the purpose of measuring the depth of the uterine cavity or for locating the position of the fundus, as it is generally used, it is absolutely superfluous; any one who is forced to use it for these purposes, excepting in rarely exceptional cases, must confess to himself his lack of even an ordinary amount of manual dexterity. For replacing a displaced womb it is a dangerous instrument and its use is very painful. A movable uterus can be invariably replaced by bi-manual manipulation, with the patient on the back, or in the knee chest position, with the aid of a tenaculum and a repositor. If the organ is adherent it no longer comes under the head of simple uterine disease and should then be dealt with by other and safer procedures. The instrument may be used with perfect safety in careful hands, but as ordinarily employed it is capable of causing considerable traumatism and of carrying septic material into the uterine cavity.

Dilatation.—This operation is one which has been much abused. It is capable of much good or much harm, depending upon whether it is used carefully and in suitable cases, or not. Personally, I have never had any permanent bad results follow its use. On the contrary, I have seen severe dysmenorrhœa relieved and even permanently cured; in not a small proportion of cases have I observed pregnancy follow dilatation. Patients have come to me suffering from a pelvic inflammation following a dilatation, performed by others, but everything pointed to the fact that the pelvic disease had existed first and that the operation had been performed, probably under a mistaken diagnosis, for the relief of symptoms produced by the diseased appendages. In but one case have I had an inflammatory attack follow this operation when there was no complicating disease. In that case I made an incomplete dilatation without ether, upon the dis-

pensary table, in a young woman, married for five years and sterile. The inflammatory attack cleared up within a week, she soon conceived and a month ago I delivered her safely of a large, healthy baby. She made a perfect and uncomplicated recovery. I should be exceedingly loath to discard the dilators from my armamentarium, and can only attribute serious accidents following their use, to a wrong diagnosis or a faulty use of the instrument.

Intra-Uterine Medication.—There is undoubtedly a limited field for the application of drugs to the uterine cavity. It should not be forgotten, however, that it is often only supplementary to other treatment. It is just as rational to expect results from local applications to the uterine mucous membrane, as from applications to the mucous membrane of the nose and throat. The fault here is much the same as in the other minor operations; either a wrong diagnosis is made, and local applications are used to the exclusion of other and probably better methods of treatment, or they have been injudiciously and rudely applied. Certainly in a chronic endometritis we may expect some good from them, especially after the application of the curette.

The Curette.—This instrument, in properly selected cases, is invaluable. In my own hands the dull curette has proven worthless and I much prefer a sharp one. Of course the instrument is capable of harm, but so is every other one used in surgery. If even ordinary precautions are taken in selecting cases and manipulating the curette, no damage will follow its application. For affections of the endometrium following labor, or of a fungoid character, it is exceedingly useful; I know of nothing which will take its place. In removal of retained clots, etc., in the puerperium the finger will be found to be more certain.

Operations on the Cervix.—The splitting up of the cervix for dysmenorrhœa and sterility has fallen into deserved disuse: all that can be accomplished in that direction, can be done with the dilators. Emmet's operation for the closure of lacerated cervix should meet much the same fate, at least in the vast majority of cases. The only excuse for the number of such operations which are being continually performed, is a fear of subsequent cancer. A simple uncomplicated cervical tear, causes no more trouble or inconvenience to the patient, than does a woman's ear which has been torn through by her earring. The ear would be repaired for cosmetic effects; the cervix is hidden from view, and that factor would not come into consideration. Most women have lacerations of the cervix of more or less degree. If the lips are thickened, everted and eroded, they will need treatment. Often-times simple scarification, followed by the application of iodine and glycerine tampons, will re-

duce this condition and leave a clean, healthy tear; one which will remain so until the end of time. If the lips cannot be brought into a healthy condition or if the uterus is subinvolved and the endometrium diseased, the case may resolve itself into an operative one; but even here a trial with electricity will often disappoint the surgeon. In my practice it is rare to see a lacerated cervix which calls for surgical repair. Cases which come to me from other men, who have advised an operation, get well without it. Oftentimes the symptoms, for which the operation was proposed, were found to be due not to the torn cervix at all, but to other troubles, principally constitutional.

It is the easiest thing in the world to relight a pelvic inflammation whilst repairing a cervix, and I have seen this result follow such practice only too often.

Taking it all in all, I decidedly approve of minor uterine surgery in the field to which it is applicable, but it must be borne in mind that this field is a limited one, and one which becomes more and more narrow as our diagnostic resources increase.

THE RELATION OF CONCUSSION OF THE BRAIN AND SPINAL CORD TO IN- FLAMMATORY AND OTHER MORBID CONDITIONS IN THESE ORGANS.

Read in the Section of Surgery and Anatomy at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 5, 1891.

BY B. A. WATSON, A.M., M.D.,

CONSULTING SURGEON TO THE BAYONNE HOSPITAL, SURGEON TO JERSEY CITY HOSPITAL, ETC.

It is certainly apparent to all the members of the medical profession that brain and spinal surgery has received during the last quarter of this century an unusual and likewise unprecedented amount of attention. It is likewise equally apparent that great progress has been made by those who are devoted to this branch of surgery; it therefore becomes highly necessary, that he, who is about to enter this field of medical literature, should first discover some dark spot or disputed question, on which he thinks he may possibly throw a few rays of scientific light. The traumatism of the brain and its membranes have been more fully studied than those of the spinal cord. Undoubtedly this may be accounted for in part by the fact, that the first mentioned organ is much more frequently the seat of these lesions than the latter. I shall therefore direct the greater portion of my attention especially to any lesions following traumatic injuries of the spinal cord and its membranes.

It seems necessary to call attention to certain

errors as a preliminary to the consideration of our first inquiry. One of the most important of these has been expressed by Mr. Erichsen in the following language:¹ "The consideration of the effects that may be produced on the spinal cord by *slight blows*, whether applied to the back or to a distant part of the body, is not altogether a matter of modern surgical study arising from the prevalence of railway accidents, but had, long antecedent to the introduction of modern means of locomotion, arrested the attention of observant practitioners." Since the above statement was made it has been clearly demonstrated to be erroneous by anatomical and experimental investigations. The anatomical studies have shown that the spinal cord is the best protected organ in the body, and experimentation has fully confirmed this position. The experiments which I made on dogs—the total number being 141—which were arranged and conducted for the especial purpose of producing concussive lesion in the spinal cord and its membranes fully convinced me that it required a *very severe blow*, which must even be delivered on certain limited areas of the body, in order to accomplish this object. I am likewise satisfied that this conclusion must necessarily follow a careful study of my report entitled "An Experimental Study of Lesions Arising from Severe Concussions."²

It should be furthermore stated that the lesions produced in the spinal cord and its membranes were rarely apparent to the unaided eye, but were readily revealed under the microscope. This statement, however, does not apply to those cases in which there were either fractures or dislocations involving the vertebræ; since the lesions here were comparatively coarse.

The statement that a rupture of the spinal membranes has occurred, or that there has been a gross hæmorrhage into the substance of the spinal cord, or between the cord and its membranes, is certainly not entitled to credence unless coupled with the acknowledgment of either a fracture or a dislocation of a vertebræ. This statement is based on my examination of the lesions found in the spinal cord, and its membranes, and I am so thoroughly convinced on this point, that I feel fully warranted in making this positive statement. The so-called "railway spine" includes true concussion arising from blows, falls, gunshot wounds, lightning strokes, electric shocks, etc., likewise contusions on the back, sudden flexions of the spinal column, sprains, wrenches, and twists. Dr. John A. Lidell says, in discussing the consecutive effects of some of these injuries, that:³ "Among the remote effects of *sprains, wrenches and twists* of the spinal column, are chronic *inflammation of the vertebral*

¹ On Concussion of the Spine. A New and Revised Edition. London: Longmans, Green & Co., 1882.
² P. Blakiston, Son & Co., Philadelphia, 1890.

joints that are implicated, which is, often suppurative in character, *destruction of the articular cartilages and the intervertebral substances* that are involved, and *caries or necrosis* of the adjoining vertebral bodies." In such cases, the destructive process begins more frequently at the junction of the vertebræ with the intervertebral substances than in the intervertebral substances or vertebræ themselves, because, as Mr. Hilton has pointed out, we know that in accidents, at least as far as we have been able to discover, "the most frequent lesion in injury to the spine is a partial severance of the vertebræ from the intervertebral substance."

A number of illustrative examples have already been presented, and inasmuch as this topic has already been pretty thoroughly discussed, no apparent need exists for presenting any additional instances of the same sort. I will, however, take space to present a very instructive case, in which there simultaneously occurred lumbo-sacral abscess and suppurative spinal meningitis, in consequence of a blow on the spinal column.

The following abstract made from the report of the history of this case supplies the essential points: A healthy lad, of 15 years, was struck by his playmate on the back with the fist. He thought little of it at the time, but was admitted to Guy's hospital nine days afterwards; was treated with leeches and somewhat recovered, but the pain soon returned and fever ensued. "An abscess formed on the right side of the sacrum, which was opened, and continued to discharge, the flow of pus being increased by pressure on the abdomen. He continued to get worse daily, having much irritative fever and severe pain in the back. During the last week of his life he was exceedingly restless, and often delirious; and he complained of pain in all parts of his body, but particularly in the extremities. On one or two occasions he had loss of power over the bladder and rectum, but had no other symptoms of paraplegia, and could move freely in bed." He died twenty-two days after the casualty.

Autopsy.—An aperture in the integuments at the right side of the sacrum led into a very extensive abscess, external to the peritoneum, which occupied the forepart of the sacrum behind the rectum, and external to the ilia on both sides behind the psoas muscles. The bones were exposed but not diseased. Although the abscess had discharged externally on the right, it was most extensive on the left. It had burrowed up to the left side of the last lumbar vertebra and the sacro-vertebral foramen into the spinal canal. When the theca was opened, it was found to contain a quantity of greenish pus, spread over its inner surface and over the cord itself. The spi-

nal dura mater (theca) at the point indicated, was softened and destroyed, and the cauda equina was lying bathed in pus which filled the sacral canal. The membranes of the cord were inflamed throughout the whole extent, and there was purulent effusion as high as the dorsal region. The spinal dura mater was thickened, and its inner surface had lost its smoothness and transparency, and was of a dull green color. Pus could be squeezed out from beneath the visceral arachnoid in considerable quantity. The spinal cord itself was firm, and the microscope revealed no morbid condition in its substance. On opening the cranium, traces of acute arachnitis were found over the whole surface of the brain, greenish-colored lymph being effused into the sub-arachnoid tissue, especially at the base. The inner surface of the dura mater, around the foramen magnum and on the adjacent part of the occipital fossa, was of a greenish color, from lymph effused upon it. Bronchial tubes filled with tenacious mucus. Lumbar and bronchial glands slightly enlarged. All other organs entirely healthy.

The purulent infiltration of the spinal meninges which was observed in this case, occurring coincidentally with the formation of a lumbar-sacral abscess, but without the production of paralysis, could scarcely have happened unless the sacro-vertebral articulation had previously been opened, both externally and internally, by disease of the articulation itself, in such a manner as to allow the products of inflammatory action to flow freely out of it, as well as into the spinal canal. Otherwise the suppurative meningitis would pretty certainly have caused paralysis by compressing the spinal cord with its inflammatory products.

The clinical history of this lad's case, interpreted by the post-mortem appearances, appears to have been as follows: The blow on the back wrenched the sacro-vertebral articulation, and caused a suppurative inflammation to be lighted up therein, particularly on the left side; and in consequence of this, purulent matter escaped in an outward direction, and led to the formation of an immense lumbo-sacral abscess; it likewise escaped in an inward direction, and caused the theca vertebralis to become softened and perforated, and extensively destroyed, and a diffuse suppurative inflammation, which extended upward to the brain, to be kindled in the spinal arachnoid.

It has been aptly said that "in all science error precedes the truth, and it is better it should be first than last." I have cited the case reported by Dr. Lidell, with all its details, in order that I might bring forward some of the results of my observations, made during my recent experiments, which afford a correct and rational explanation of the conditions revealed by that post-

mortem examination. There will be found in the report of my experiments eleven cases in which there was rupture of the ligaments of the sacro lumbar articulation. There were marked pathological changes in the organs and tissues within the pelvic and abdominal cavities in six of these cases, which were immediately connected with the rupture of the ligaments of the sacro-lumbar articulation. Let me here present the following abstracts from post-mortem examinations, for the purpose of giving a correct idea of the lesions:⁵ "Autopsy. This examination revealed a rupture of the ligaments between the last lumbar and the first sacral vertebræ, deep and extensive ecchymoses over the entire post-sacral and right lumbar regions. A profuse extravasation of blood into the abdominal cavity, marked engorgement of the kidneys. Brain apparently normal, slight increase of the cerebro-spinal fluid in the cavities, and the cord was congested, to the middle of the dorsal region."

"Autopsy.⁶ This examination revealed the following lesions: Both kidneys congested; ecchymosis in the connective tissue covering the anterior surface of the last lumbar and the upper sacral vertebræ. The brain and spinal cord apparently hyperæmic. The removal of the integument over the sacral and lumbar regions showed an ecchymotic condition of the muscles. There had been a rupture of ligaments between the last lumbar and upper sacral vertebræ."

"Autopsy.⁷ This examination revealed the following lesions: Both kidneys congested; bladder distended with urine; extensive ecchymoses in the lumbar and pelvic regions, involving psoas muscles; brain perfectly normal. The spinal cord was hyperæmic downward from the lumbar enlargement, including a portion of the caudæ equina; rupture of the ligaments between the last lumbar and the first sacral vertebræ." The essential point which Dr. Lidell has overlooked in his comments on the case which he has reported, are the pathological conditions of the organs and tissues within the pelvic and abdominal cavities. It was the *existence of these lesions which gave rise to the inflammation and suppuration* within these cavities. The post-mortem examination of Dr. Lidell's case sufficiently demonstrates this position. Dr. Lidell says:⁸ "the blow on the back wrenched the sacro-vertebral articulation, and caused a suppurative inflammation to be started up there." The autopsy in the case fails to show that there is any erosion of the bones or cartilage within this articulation, and its history reveals the fact, that it was only immediately before death that there was the slightest indication of paraplegia. It is therefore certain that the

wrench which he mentions consisted in producing a rupture of the ligaments of the sacro-lumbar articulation, and likewise, as very frequently happens in those cases, some pathological lesions within the pelvic and abdominal cavities. The simple wrenching of any joint in a healthy subject unattended with pathological lesions, has been amply shown to be a comparatively trivial injury, which does not lead to serious inflammatory complications or death.

The one hundred and forty-one experiments, which I made on animals, does not afford a *single example* which justifies the conclusion that injuries to the vertebral articulations are a whit more serious than those produced in the carpal and tarsal articulations; and, consequently, analogous reasonings may be here employed with entire propriety. We cannot pass over the history of Dr. Lidell's case without pointing out a glaring absurdity, which may possibly have had its origin in carelessness. In this report we are informed that a healthy boy, aged fifteen, "while playing with another lad, received a blow on the back with the fist," and in the absence of any additional statement bearing on this injury, we are left to infer that the pathological changes and even the death of the patient were directly caused by this blow. He who has examined the anatomical structure of the spinal column will readily perceive the absurdity of this statement. *The blow inflicted was entirely inadequate to the production of the results* which followed, unless there has been omitted from this report the most important factor in the history of this case. It is true the force of the blow might cause the lad to fall—and if at this point, the history of the case showed that the boy fell across a bar, raised a few feet from the ground, in such a manner that his feet remained on one side while his head was on the other, then the very important factor of leverage having been added, which would result under these circumstances in the production of a sudden flexion of the spinal column, would certainly bring within the limits of possibility the occurrence of the injuries which are reported in the autopsy.

It is scarcely necessary to mention the fact, that nearly all the injuries grouped together under the unfortunate cognomen of "railway spine"—so far as their remote effects are concerned—take their origin, either directly or indirectly, in inflammatory processes. Consequently the consideration of the following queries assume importance:

1. Do inflammatory and other morbid changes take their origin in traumatic injuries of the spinal cord and its membranes as frequently as the writings of Mr. Erichsen imply?

2. Do inflammatory and other morbid changes ever arise from traumatic injuries which are entirely uncomplicated by immediate symptoms?

⁵ An Experimental Study of Lesions Arising from Severe Concussions," by B. A. Watson, A.M., M.D., p. 32, Exp. 4.]

⁸ Previously cited.

3 How soon are the inflammatory and other morbid changes developed after the receipt of traumatic injuries in the cord, etc.?

In our consideration of the first question it is scarcely necessary to give a negative reply to those who have perused the writings of Mr. Erichsen on this subject; since they have already reached this conclusion. Furthermore, the mere assumption that serious results frequently arise from wholly unimportant injuries *is not sustained* by clinical observations or experimental investigations. However, Mr. Erichsen, in writing of those cases in which the patient has received no blow or injury upon the head or spine, but in which the whole system has received a severe shake or shock, in consequence of which an immediate lesion, probably of a molecular character, is sustained by the spinal cord, and disease of an inflammatory character, or of a disorganizing nature, is developed in it, the inflammatory action eventually creeping up to the membranes of the brain, says that the cases "although *necessarily more frequent* in railway than other injuries, do occasionally occur as a consequence of ordinary accidents." A perusal of Mr. Erichsen's writings has completely failed to convince me that he has supplied any basis for the support of the opinion advanced in the above statement.

In order to demonstrate the correctness of this opinion, which conflicts with the positive knowledge we possess on this subject—and which cannot be supported by analogous reasoning—he should clearly establish the following facts, viz.: 1. *That no disease of the brain or spinal cord existed at the time of the occurrence of the alleged accident.* 2. *That the consecutive inflammation did arise from traumatism, and was not due in part, or wholly, to a vitiated constitution.* This evidence is entirely wanting; and, consequently, we must maintain that Mr. Erichsen's statement should be excluded in cases of medico legal evidence.

We have now devoted our attention to the consideration of the material points involved in our first query; but it would seem proper in this connection to give some additional thought to the consecutive results of concussive accidents. Mr. Erichsen says:⁹ "Whatever may be the nature of the primary change that is produced in the spinal cord by a concussion, the secondary effects are clearly of an inflammatory character, and identical with those dependent on chronic meningitis of the cord and sub acute myelitis." The term concussion, as employed in the above quotation, evidently refers only to traumatism of the spinal cord and its membranes, but elsewhere the same author in speaking of sprains, twists and wrenches of the spinal column, says,¹¹ "It is im-

portant to bear in mind that the vertebral column is more apt to suffer in these strains of the spine than in the other forms of injury that we are discussing, and that in serious cases the full force of the mischief appears to be expended in the spine itself independently of its contents, which escape uninjured." The views expressed by Mr. Herbert Page on this subject are as follows:¹² "Happily there is no doubt of the exceeding rarity of spinal meningitis as an immediate result of localized injury to the vertebral column; and I know of no case in which meningeal inflammation has been caused by injury of some part of the body remote from the spine." The experimental study of concussion of the spinal cord has satisfied me on the following points: 1. True concussion of the spinal cord from blows, falls, lightning strokes, etc., is an exceedingly rare occurrence. 2. Secondary results, such as inflammation, suppuration, etc., very seldom follow the traumatism—owing to the fact—that the punctate hæmorrhages, etc., are generally widely diffused in various parts of the spinal cord—while the pathological lesions are so slight as not to supply inflammatory foci. However, the danger arising from a true concussion of the spinal cord produced by gun-shot injuries, the lodgment of a musket or rifle ball in the spinal column, is attended with much more danger from consecutive inflammation, etc., than those traumatisms which have been previously mentioned, because of the following peculiarities: 1. The pathological lesions are more concentrated—resembling in this respect the ecchymoses arising from a concentrated contusion. 2. The lodgment of a ball in the spinal column is very liable to give rise to a septic inflammation, pus formation, diseased condition of bone, extension of the inflammatory products to the spinal membranes, and even the cord itself. It must be universally admitted that gunshot wounds, fractures and dislocations involving the spinal column, are very serious traumatisms, frequently producing death immediately, or within a few hours; even when this result does not follow, the danger is very great from the consecutive sequelæ.

Let us now take up the consideration of the second query: "Do inflammatory and other morbid changes ever arise from traumatic injuries which are entirely unaccompanied by immediate symptoms?" The conclusions reached by a careful analysis of the above question, must depend, to some extent, on the interpretation which we give to this query. The fact must be admitted that it is not only possible for a patient to receive, under certain circumstances, severe traumatic injuries, of which he remains a longer or shorter period wholly unconscious, and these occurrences are by no means very rare. I can

⁹ On Concussion of the Spine, Nervous Shock, etc., p. 95. New York: Wm. Wood & Co. 1875.

¹⁰ *Ib.*, page 157.

¹¹ *Ib.*, page 128.

¹² Railway Injuries, page 21. Philadelphia: P. Blakiston, Son & Co. 1891.

now recall a number of instances of this character occurring to officers and soldiers during the excitement of battle, while I was serving with the army. It also occasionally happens that drunkenness dulls the sensibilities in certain cases to such an extent as to render the patient oblivious to an injury which he may have received, while the same condition will more or less embarrass and sometimes even deceive the surgeon who is attempting to make an examination. These statements possess only an indirect bearing on the question under consideration. The question relates to the immediate existence of symptoms and not to the observance of the same. A critical examination of this question in the same direction indicated in the above sentences, brings us to the following query: "Are results ever produced without causes?" *i.e.*, "Do inflammatory and other morbid changes ever arise from traumatic injuries, which have failed to produce any lesions?" My experimental studies of the lesions of the cerebro spinal axis have clearly demonstrated the fact, that pathological changes are occasionally produced in this centre, some of which were even apparent to the unaided eye, while others required the aid of the microscope; but which were not followed by any symptom indicative of these lesions during the life of the animal. The question will now be naturally asked with reference to these cases: Would they not have developed inflammatory changes at a later period? I have not before me the data which would justify me in positively asserting that a result *was absolutely impossible*; but I can aver that, in all these experiments, one hundred and forty one, there is not a single case which warrants giving an affirmative answer. Surgical observations and analogous reasoning fully support the results obtained by our experimental research, not only with reference to the brain and spinal cord, but likewise in other organs of the body. Mr. Erichsen says in his recent work "On Concussion of the Spine:"¹³ "There is a continuous chain of broken ill health, between the time of the occurrence of the accident and the development of the more serious symptoms. It is this that enables the surgeon to connect the two in the relation of cause and effect. This is not peculiar to railway injuries, but occurs in all cases of progressive paralysis after spinal concussion." It would appear from this quotation that Mr. Erichsen fully concurs with us in the opinion, that the production of a traumatic pathological lesion is always indicated by immediate symptoms, when the degree of injury has been sufficient to entitle it to our consideration. Observation has taught us that the existence of a pathological lesion affords insufficient proof that this injury will be followed by inflam-

mation or other morbid changes. In fact, every surgeon can recall to mind cases of severe traumatic injuries of the brain in which there were extensive lacerations or contusion of this organ; but in which the secondary changes were entirely absent or very slight.

The same remark may also be made in regard to gross injuries in other parts, since the same general physiological and pathological principles prevail in the cerebro-spinal axis as in the other organs of the body. It is therefore entirely proper to introduce in connection with discussions of injuries of the cerebro spinal axis, in many cases, analogous reasoning drawn from studies and observations made in other parts of the body. It must be admitted, as a general rule in surgery, that the more extensive and the more destructive the primary traumatism, the greater will be the danger from secondary disorganizing processes. Does it not, therefore, seem absurd to attribute to a single punctate hæmorrhage, or even a half dozen of these little pathological lesions, the power of exciting a disorganizing process in a *healthy spinal cord* which may ultimately produce the death of the patient? Is there a single well authenticated case in which such a result has followed from such a cause?

Let us now proceed to the consideration of our third question, which has a very important bearing on medico-legal cases and likewise on the diagnosis and treatment of myelitis arising from syphilitic disease. Mr. Erichsen says:¹⁴ "It would appear that surgeons and writers on diseases of the nervous system have included four distinct pathological conditions under this one term, 'concussion of the spine,' viz.: 1. A jar or shake of the cord, disordering, to a greater or less degree, its functions without any lesion perceptible to the unaided eye. 2. Compression of the cord slowly produced by the extravasation of blood. 3. Compression of the cord by inflammatory exudations, serum, lymph, or pus within the spinal canal; and 4. chronic alterations of the structure of the cord itself as the result of impairment of nutrition consequent on the occurrence of one or other of the preceding pathological states, but chiefly on the third."

We have already paid our respects in full to those subjects included under the headings 1 and 2, but we have yet to deal with those embraced under headings 3 and 4.

There exists no reason to doubt that inflammation, having its origin in the spinal cord or its membranes, may be either acute or sub-acute, or that the former need be developed at an earlier day than the latter. The important question before us for our consideration, however, is how soon do traumatic inflammations arise after the receipt of the traumatism? This question can

¹³ A new and Revised Edition, page 158. London: Longmans, Green & Co., 1882.

¹⁴ On Concussion of the Spine, p. 16. London: Longmans, Green & Co., 1882.

not be definitely answered—the answer must necessarily be a mere approximation. Nevertheless, I think that observation and experimentation fully justify the statement that traumatic inflammation commonly makes its appearance within four days after the receipt of the injury. In support of the above I will here present a series of experiments, which consisted in fracturing the right leg of twenty rabbits:¹⁵ "This was done without producing a single compound fracture. The temperature details were as follows: Average temperature before the fracture, 102.6°; average temperature two hours afterwards, 102.6°; subsequent daily average temperature, first, 102.6°; second, 102.6°; third, 103.1°; fourth, 103.1°; sixth, 103°; eighth, 103.1°; tenth, 102.8°; twelfth, 103°; fifteenth, 102.8°; seventeenth, 103.2°; nineteenth, 103°; twenty-second, 103°."

In the case of the brain and spinal cord, when there is no open wound communication with these organs, the danger of inflammatory action is greatly diminished. Furthermore, the trivial character of lesions produced by concussion, *and also the exceeding rarity of this traumatism*—except when it is produced by lightning strokes, electric shocks or gunshot wounds—all combine to impress me with grave doubts in regard to its being followed by inflammation. In fact, *there is not sufficient proof to justify the conclusion* that any case of traumatic myelitis, or meningo myelitis, has ever had its origin from molecular disturbances or any pathological lesion which was invisible to the unaided eye in an otherwise healthy spinal cord or its membranes.

Let us now briefly examine the history of concussion, in order that we may, if possible, discover how these troublesome errors were engrafted on the profession. The history of concussion dates from 1705, when M. Littre published his famous observations. A prisoner struck his bowed head against the wall of his cell and fell dead. The inspection of the head failed to reveal a contusion, tumor or wound in the scalp, or a fracture of the skull. The cranium was opened, when it was discovered that the brain did not nearly fill the interior of the skull, while the entire brain substance seemed harder to the touch—more compact than usual. This observation has been reported hundreds of times, and it was long claimed that it demonstrated the fact that a violent shaking of the substance of the brain was capable of producing death without any appreciable lesion. Permit me here to call attention to the fact that in the report before me there is no evidence to show that there was any post mortem examination made of any portion of the spinal column, spinal cord or its membranes, or other portion of the body, except the

head. The autopsy of the head, viewed in the light of modern science, is entirely worthless, while the position in which the head was placed at the moment the injury was inflicted suggests the possibility of a fracture or dislocation in some portion of the cervical region of the spine. It may be well to call attention to the fact that in this case, and all the other cases of concussion reported prior to the middle of the present century, the microscope was not employed to aid in the discovery of the pathological lesions. Post-mortem examinations were very rarely made even in cases of concussion of the brain, and, consequently, the case reported by M. Littre was accepted as a typical one. M. Littre, at the time he reported this case of so-called concussion of the brain, had become famous in the medical profession and therefore the following may be very properly applied to him: "Great errors seldom originate but with men of great minds."—Petrarch. Mr. Erichsen, in writing on concussion of the spine, in 1875, remarks:¹⁶ "There is little opportunity, reason, or excuse for a post-mortem examination of that structure, which is probably the one that is least frequently examined in the dead house, viz, the spinal cord, as it is the one the correct pathological investigation of which is attended by more difficulties than that of any other organ of the body. . . . So rare are post-mortem examinations of these cases that no instance has occurred to me in hospital or in private practice in which I could obtain one, and with one exception, I can find no record in the transactions of societies or in the periodical literature of the day of any such instance. The only case, indeed, on record with which I am acquainted, in which a post-mortem examination has been made of the spinal cord of a person who had actually died from the remote effects of concussion of the spine from a railway collision, is one that was published in the 'Transactions of the Pathological Society,' by Dr. Lockhart Clark. He had been in a railway collision, and without any sign of external injury, fracture, dislocation, wound, or bruise, began to manifest the usual nervous symptoms. He gradually became partially paralyzed in the lower extremities, and died three years and a half after the accident." There is no reason to believe that this man died from even the remote effects of the traumatism. The history of this case entirely fails to connect the disease from which the patient died with the railway collision. Therefore it may be properly said of those who base an argument on this and all similar cases:

"When people once are in the wrong,
Each line they add is much too long;
Who fastest walks, but walks astray,
Is only farthest from his way."

—Prior.

TUBERCULIN, THE VALUE AND LIMITATIONS OF ITS USE IN CONSUMPTION.

Read before the Colorado State Medical Society, June 17, 1891.

BY CHARLES DENISON, A.M., M.D.,
OF DENVER, COLORADO.

I assume that no apology is necessary for my changing the subject of this paper from the Surgical Treatment of Lung Cavities to the discussion of Koch's lymph; because of late my mind and opportunities have been turned in the latter direction. Besides, my professional brothers expect some report of my investigations of the great German scientist's new remedy, and now and here are the best time and place for it. Now, because time enough has elapsed for the expression of a great variety of opinions, and here, because no *symposium* on consumption is complete without a consideration of this recent invention for its amelioration.

The questions which to my mind need most to be answered are,

1. Was the description given us of the composition of Koch's lymph sufficient for our gaining full knowledge as to its uses?

2. Were the rules laid down by the author adequate and complete enough for the use of so powerful an agent?

3. Is the knowledge of tuberculosis sufficient, or are the means and facility of its diagnosis adequate among the average of medical men for their use of tuberculin, as proposed by Koch, without a considerable chance of damaging the patients, as much as they would benefit them?

I have arranged these questions purposely that I might answer them as I do, with a decided No. It must then follow that this is not yet a remedy to be indiscriminately sold by druggists, and generally used by all sorts of doctors.

The much to be desired time will come, if this remedy is not too soon consigned to oblivion, as it was at first placed on the top of the Mountain of Hope, that the knowledge of tuberculin and of tuberculosis likewise, will be adequate to satisfy a critical mind. But that time is not yet.

Nevertheless, with all these doubts and suggested limitations, the use of tuberculin, though unconsciously faulty, is not to be forbidden, if we can show that we are running only a ten to twenty per cent. chance of danger for the purpose of a thirty to sixty per cent. chance of benefit. The reason for this discussion is thus apparent, that through the process of exclusion, conditions only favorable to the use of tuberculin may obtain, and the percentage of danger be reduced to the minimum.

This criticism of the German professor's methods must not be considered as an under-valuation of that scientist's true worth. Robert Koch stands to-day without a living peer in the great

and growing profession of medicine, for he has originated more for scientific advance than any two men living. He has not only discovered the bacillus of tubercle so that physicians all over the world could easily demonstrate it as an essential feature in every tuberculosis, but in a few years thereafter he has produced a fluid which wars against the *habitat* of that germ, thus tending to eliminate its consequent disease. When we reflect that tuberculosis exterminates more of the human race than any other disease under the sun—that is, ever since Jenner's vaccine virus "knocked out" small pox,—we say all honor to Robert Koch, the greatest physician of the age.

We would, if possible, find out the inadequacies or mistakes in Prof. Koch's procedure, that the perfection of his great discovery might be brought nearer to hand. For I believe that rightly directed criticism will do much to clear away the doubt and prejudice which largely pervades the professional mind as to this means of cure.

Let me then consider the questions previously propounded, and see why they should be answered in the negative. I will use the cases I have experimented on for purposes of corroboration or reference, and try not to burden your minds or patience too much with their many details. We shall confine our attention wholly to pulmonary cases. These cases have been twenty in number. Numbers one to five of these most people would call cured. I do not yet claim that term as applicable, yet they are probably better off than in a state of arrest, because the tuberculosis has been in a process of elimination. These twenty cases were serious enough; distinctly tubercular, yet only two of them acutely so.

Nos. 1, 2 and 3 were third stage cases, with both lungs more or less affected, while Nos. 2 and 3 had the dreaded laryngeal complication.

No. 4 is interesting, as showing the diagnostic power of tuberculin. This was a case of fibrosis chiefly, evidently tubercular when he came to Colorado for his health three years previous. In March, 1891, his disease was apparently fully arrested, through the fibroid process and rarefied air. The question then arose, could he go back East to live? I obtained from his parents permission to use the tuberculin to learn if latent tuberculosis remained. I was much surprised to find a considerable local reaction in the right infra-scapular space, where previous to the first injection I had not noticed anything abnormal. This reaction was over an area two by three or more inches, and was accompanied by the characteristic febrile rise to 101°, and the appearance of bacilli in his sputum, (four to the field) which had not been found by a previous microscopic examination. This reaction, which was marked after 2, 4 and 6 mgs., wore off with the lessening of fever as larger doses were reached. Finally there was no reaction after 20 mgs., and I con-

sented to his return to Massachusetts after a 30 mg. dose and about six weeks treatment. The characteristic rough breathing in the rear base of the right lung had moderated, assuming the slightly bronchial character usual in high altitudes in an arrested fibroid lung.

Case 5, of my list, is to me very interesting, because it shows the undoubted agency of climate and lung ventilation in the cure, as well as the rapidity and ease with which his system took the tuberculin. Mr. F. T. P., age 27, a lawyer from Toledo, Ohio. In January, 1890, had had la grippe, followed by weakness, night sweats, cough and loss of 15 pounds in weight. In March went to Asheville, N. C. Was thin and had decided p. m. hectic there for some time. Began to gain flesh in October. Arrived in Colorado October 18th, weight at least in summer 133 pounds. October 20, 150 pounds. Temperature ranged between 98° morning and 100° evening. Spirometrical record 240. Manometer 85 M.M. Expansion 33 and 36. Sputum yellow, one-half cup chiefly mornings. Depression, moist râles on coughing, and almost "cracked metal" on stethoscopic percussion below right clavicle. Waivey and broncho. Vesicular respiration in left infra-mammary and lower axillary. All showing softening (2d stage) at right apex and arrested fibroid process at base of left lung.

May 7, after spending the winter, much out of doors, in Colorado Springs, all the physical signs were found to be improved. Expectoration less one-third cup in 24 hours. Expansion increased 1 inch, 32½ and 36½. Fewer râles at right apex. Bacilli in sputum, some slight, probably compensative, emphysema in lower half right lung.

May 15, began tuberculin injections. Bacilli five to field, no general reactions (*i. e.*, no fever), but slight local reactions shown by physical signs, so a rapid increase of dose was allowable, *i. e.*, nearly doubling every other day.

May 23, after 10 mg., thirty bacilli to field.

June 2, after 45 mg., three or four scattered bacilli to the field, but still with slight remaining indications of the effect of the tuberculin local reaction, the characteristic harsh breathing in right infra-clavicular and left infra-scapular regions. Pulse, respiration and temperature normal, expansion 32½ and 37 inches. He declared he was well, and was bound to go home, to Toledo. I could not restrain him, and so with a parting 50 mg. "shot," let him go, with the advice that he return, work up to 80 mg., and then thoroughly establish his cure by camping in the mountains during the hot months of the summer. We shall see. A letter just received from him says he does not feel as well down in Ohio, and he may return. These five cases have all lost the usual signs of tubercular state, have increased in vigor and no longer react to large doses of tuberculin, 30 to 50 mg. Their sputum,

diminished to the minimum in quantity, shows only the remnant of the vanquished bacillary army which was making war on the organism, at the commencement of this treatment, four months ago.

Numbers 6, 7, and 8 are now under treatment, and will soon arrive at the favorable state of those previously mentioned. They are progressing evenly and finely. These are, No. 6 a lady from Greeley, with broncho fibro-tuberculosis, having a very small softened or bronchiectic spot in each lung, now completing a mid way rest in the treatment at 30 mg. (Since reached 60 mg.)

No. 7, a tolerated third stage fibro-tubercular case, with large cavity in left apex, who has slowly reached 7 mg.; and No. 8, a more decidedly tubercular fibroid case, both lungs affected, with a bronchiectasis in the left and a softened spot on the right, and considerable dissemination of the fibroid process. He is now getting used to 1 and 2 mg. One mg. tuberculin was too much for this patient at first, and four lesser doses had to be given before the reaction satisfied me as sufficiently mild. Nos. 9 and 10, lately commenced a cautious or tentative plan of treatment, and are third stage cases progressing satisfactorily, but the final result is not yet in sight. No. 9 is a case of laryngeal phthisis, and a process of healing can already be noticed in a tubercular ulceration on the left side of the pharynx.

Nos. 11 to 14 inclusive have ceased treatment temporarily for reasons given. They were favorable cases, however, and reached an average of 10 mg. for last treatment. These four were all third stage cases, the evidence of that advance being very positive with large cavity in one case, much less positive, and in a small space in the others. I cannot consistently, with my notions of truth, classify the consumptives we have to deal with in Colorado and put many in the second stage. If softening has occurred that is usually the end of it, and it is the result in the third stage with which we have to deal.

Of these four, Dr. —, of Idaho Springs, reached 14 mg. and reacted slightly at that increase; lost his fever, and gained in strength and physical signs. The effect of the tuberculin in shrinking of affected lung tissue was manifest in his case. The highest reaction was 102° F. after 4 mg. March 8, after he returned home to his practice, he continued every other day 8 to 10 mg. injections himself. March 26, he wrote that his temperature had been above normal but one day, and that was due to extraneous causes and not to injections. He says he took the injections regularly "without experiencing the slightest reaction or discomfort. So far as symptoms go I feel as well as I ever did. Think my cough is about the same, but expectoration less. Am sure the expectoration has lost much of its puru-

lent character. Am still taking the tuberculin On the whole I feel that I am deriving benefit from the treatment, and would like to continue with increased dose if you see fit."

Case 12.—N. J. F., a laborer, aged 30. Case of tremendous cavity in left lung (see chart), reaching from clavicle to opposite left nipple, and lying on the anterior border of the lung. The regularity of his pulse 88, respiration 32, temperature 98° to $100\frac{1}{2}^{\circ}$, and my confidence in his unexcitable, steady temperament, led me to give way to his determination to try the new "lymph" treatment. I was from March 13 to April 9 reaching 9 mg., and on April 26, reached the highest point, 18 mg., when a rest of ten days was taken. Then I returned to 10 mg. at a dose, and was cautiously increasing from that point with favorable effect, when he was offered an opportunity to take charge of a squad of men working on a railroad. I believed that climate, outdoor occupation and time were as important for him as the remaining chance of benefit from tuberculin injection, and so readily consented to the change. His was, however, an interesting and exceptional case in more than one particular. His principal reaction came after the 6 mg. dose, when my attention was attracted to the characteristic rough respiration in the region of the *right* nipple, where before no abnormal sound was heard. This I have come to consider as symptomatic of the working of tuberculin in affected tissue, and is an additional diagnostic evidence which physical diagnosis alone cannot impart. Another interesting feature of this case was the seeming contraction, as the treatment progressed, of the large cavity in the left lung, due to the shrinkage of the surrounding, and probably tubercular, affected tissues. My note of the fourth recorded examination, April 23, reads, "The case has gotten along very evenly, and a marked absence of tubercular change is manifest in an even average of pulse 94, respiration 26, and temperature $98\frac{1}{2}^{\circ}$. The cavity is, if anything, less in size, and moved upward and toward the front. The lung, while somewhat inactive below and behind, shows only a few coarse râles. This closing up tendency of the lymph when acting between lung tissue and the main bronchus, is particularly applicable to the next case, No. 13, Rev. J. T. S., age 37, who had, he says, a contracted left lung, even in childhood, hæmorrhage 7 years ago, pleurisy, 6 years ago, and la grippe, winter 1889-1890.

My diagnosis of his case, April 1, when I first saw him, was fibroid phthisis, probably third stage, left (because of a small honey-combed spot under left clavicle), and first stage right. I have no doubt the poor ventilation marked on his chart at the second examination, April 6, over the lower half of the left lung, the air moving therein only a little except by forced breath-

ing, was in no small degree due to the exaggerated reactions from the tuberculin injections which were manifest around the root of the left lung. I can conceive of tuberculin having this effect in a lung elsewhere unaffected, except around the largest bronchi. The previously contracted condition of this left lung in question aggravated the effect; and headache and chilly feelings were added to the usual evidences of a decided reaction, even to as little as 3 or 4 mg. I deemed it better, therefore, that measures should be inaugurated, chiefly left arm exercise, riding horse-back, etc., which would tend to improve the use of this left lung, before proceeding farther with the Koch treatment.

No. 14 of the series, the wife of a prominent Chicago real estate owner, was also of special interest, but for reasons I have not seen noted by any other observer. The highest point reached in fifteen tuberculin injections was 9 mg., yet all decided reactions were accompanied by such temporary depression of spirits, with a chilliness, the second day afterward (she took them every three days), that a cessation was deemed advisable. She said at one time while reaction was going on, she cried four hours, she felt "so blue," yet the appetite was increased, as was the ability to exercise, and the local effects were not at all unfavorable. Curiously enough her feeling of depression of spirits while on board ship at sea had been just the same.

The other six cases need also to have each a separate reference, in order to understand why eventually each should be classified under the doubtful cases for completing the tuberculin treatment. Every serious case has some prominent feature about it which distinguishes that particular one from a thousand others.

Case 15, age 36, brick mason from Massachusetts; came with extension fibroid process in left lung, probably caused by or following tubercular softening. This process increased and was made permanent, at different times after arrival in Colorado, by typhoid fever, pneumonia and by pleurisy. The strength of the fibroid tissue was shown by his pressure record on the manometer to be the normal for a man in health, 100 mm., while his spirometrical record was only 112 cubic inches, less than one-half of what it should be for a healthy man of his height. Nervous temperament, no fever, but bacilli in sputum. By the rule I will lay down the ratio of movement of the affected as compared with the unaffected side, namely, 1 to 3, with so small a spirometrical record, makes him an unfavorable case for tuberculin treatment. His case is in arrest. Nature and high altitude climate have already accomplished what tuberculin might perhaps have done. They work together on somewhat the same lines. Of course reactions, both local and general, followed, up to the limit of 6 mg., which

was reached in his case. He, undoubtedly, had fibroid tissue enough and the course was not satisfactory. He has since been doing first rate on mercurial inunctions over the hardened lung, while camping out at about 7,000 feet elevation in the mountains.

Case 16, a young man, age 20, from Scotland, a sub acute case, diagnosed fibro-tuberculous, second stage, right, and first left. I believe the tuberculin treatment could not compass this case, for the principal reason which operates in many other serious cases, lack of ventilation of the chiefly affected lung, and also, in this case, because of a concealed septic state. Though 14 mg. were very gradually reached in the course of six weeks with some improvement, yet some times even a greater afternoon rise of temperature would be shown, 102.3°, when the tuberculin had not been given than when it had. The abandonment of tuberculin and the substitution of iodine and chloride of gold and sodium injections for three weeks, greatly controlled the fever, and he is now doing fairly well.

Case 17 I think was peculiar from the too great amount of elastic tissue in his expectoration, which followed a diminution in amount of sputum from 1 pint to 4 ounces per diem, during the first two weeks of tuberculin treatment. He was a blacksmith, age 35, from Omaha, Neb. His was diagnosed as a case of broncho-fibrosis, both lungs affected. Second stage right, and first, with large bronchiectasis left.

This case prompted the suggestion that it is possible excessively to stimulate the production of fibrous or elastic tissue, which is, of course, undesirable in those already having enough. So although bacilli in decreasing numbers were still found in his sputa tuberculin was discontinued at 12 mg.

Case 18, age 30, Secretary of a Cattle Company in Canon City, originally from Kansas for his health. A large cavity on left lung with some slight fibroid involvement of the rest of the left and part of the right lung. There was slight oozing of blood into the cavity, under one of the reactions, suggesting caution in advancing the treatment; and 12 mg. in a month was the highest point reached. In his case, other than the cavity, there was decided local improvement,—an increase and then a decrease in the number of bacilli to the field, an effect of treatment which was shown in nearly all of these cases.

Case 19.—A young man aged 24, from Kansas. Disease originally started from left pleurisy with effusion. February 17, before tuberculin treatment, the diagnosis was, left third stage, fibro-tuberculosis and catarrhal phthisis and right first fibroid. During the next four weeks 17 mg., the largest dose, was reached. The patient increasing from 128 $\frac{3}{4}$ to 135 pounds in weight, and being very much encouraged by his ability

to do and his general improvement. He then had an attack of what seemed to be la grippe, and no more injections were given. A week after this he was taken down with a very bad attack of measles. After ten days these accumulated poisons seemed to have centered in his left lung, which broke down rapidly, and he died one month after these tuberculin injections. I do not regret the course taken in this or any of the cases to whom tuberculin was administered, for accidents like that last mentioned could not be foretold, and the only disparaging claim that could be made would be that this young man was perhaps less liable to stand the peculiar poison of measles than if he had not been under the Koch treatment. Some of these patient are present for you to see them, and my charts and records of these reported cases are here for your attention if you desire it.

Case 20, much like No. 16, only worse as to febrile change and impossibility of thoroughly ventilating a contracted and partly honey combed left lung. The pneumatic cabinet might have been of use in this case in counteracting the shrinkage effect of tuberculin in upper half of the affected left lung. This, as before explained, shuts in the stagnant air and perhaps the exuded bacilli in the lung below; and such a case is not a good one for pushing the treatment.

These are the only cases to whom I have administered tuberculin, except two cases this week commenced, and a small dose of $\frac{1}{4}$ mg., given to a forlorn case for diagnostic purposes only. It was desired to know if the only remaining lung (the left) was tuberculous, and this experiment by local reaction verified the suspicion that it was. The Shurly treatment was then pushed with some good effect, but the patient died a month or two later.

On the whole, considering the very serious nature of the lung conditions in these, all of them tuberculous cases, the result of the treatment is very encouraging, as proving tuberculin to be an important aid to climatic treatment in this region; or *vice versa* if you prefer it that way.

I ought perhaps to say that during this time, covered by my tuberculin experiments, I refused or decided not to give the Koch treatment to more than twice as many patients, partly because they were unsuited, but in a majority because they were incipient cases, especially suited to our climatic treatment.

We have been asked or have ourselves desired, to use this newly discovered agent—tuberculin—without any very distinct understanding being granted us as to its composition, its strength or its mode of preparation. In view of reported adverse experiences and statements in reference to its use, this enforced uncertainty as to detail naturally suggests the inquiry: would it not have been better to have submitted the first use of tu-

berculin, with all available information with reference thereto, to carefully selected experimenters for their separate determination of rules of procedure, and then from these sources reliable directions as to detail could have been sent out to the world. As it is, we now hear of Prof. Koch reducing his initial dose in certain cases to one-tenth of his first promulgated order.

The advisability of the method employed for putting the tuberculin into use, was questionable, that is, its only being sold to hospitals. Of course one could use the friendship of the Secretary of the Interior, as I did, and get some of the "desired stuff," as he called it when he sent it to me. Nevertheless, the arbitrary restrictions to only hospital use conjoined with the directions that patients should be put to bed when reacting to the lymph, was, I believe, a mistake. It was suggestive of the use of too large doses in too serious cases, and a lack of a right conception of what was desired to be accomplished. I started out to follow the direction with a private hospital of ten beds, but soon found it unnecessary for the kind of patients who do best under this treatment. To be out of doors, riding on tramway or cable cars, even while gently reacting, was not hurtful, and my most satisfactory Koch patients were those who regularly exercised; as No. 1, who is a furniture polisher and has kept at his work ever since the first week of treatment; No. 2, who is all the time *on the go*; No. 5 ditto, whose expansion has increased to $4\frac{1}{2}$ inches; and Nos. 8 and 9, who, though reacting to less than one mg., have been averaging five to eight miles walking daily.

As to the details of the necessary examination, preliminary to commencing treatment with tuberculin, I have not time to give all the particulars. You can see my own examination chart which I here present; but I know that ordinarily some of the most essential points are omitted by the average medical man. Take the manometer, spirometer, and mensuration, for instance. The manometer, which gives information in millimetres of mercury of the strength of new elastic tissue formation in the lungs, is very seldom used; the spirometer, which has been depreciated by some of our best authors, the late Dr. Flint, Sr., for instance, is not one-tenth appreciated by the medical profession; I do not know that the bilateral movements of the chest are generally taken, and the same can be said of proper stethoscopic percussion for determining the commencement of softening or excavation of lung tissue. As I have made a careful use of these extra aids, to a proper understanding of these tubercular cases, I may perhaps be excused for referring to some thoughts which seem to me essential.

PRECAUTIONARY MEASURES AND RULES:

Understand the patient, the extent and character of his disease and its abridgement of his

respiratory capacity, or the liability to such abridgement under this treatment. For this purpose compare the chest expansion and spirometrical record with the normal for his height; and if, as is most likely, the two sides differ in movement, compare the bilateral movements with the spirometrical record of this given individual. For instance, as in case 13 of my list, the movement of the left as to the right side was as one to three, and the spirometrical record 150 cubic inches, when it ought to be 250 for a healthy man of his height. Well, if we were to calculate that the right lung does its full share it would leave only 125 cubic inches for the left, or on the basis of one to three of what was breathed, 37 cubic inches should be allotted to the left lung, and this only on forced breathing to the extreme. Of course this left lung was not ventilated. If there has ever been any softening in such a case and it has reached such a stationary stage, as the fever curve, that tuberculin would be otherwise safe to administer, then it must be that nature has been already at work through her own method of cure—the fibroid process. She has probably pasted up the lung by her plastic exudations of fibroid deposits, even to adhesions of that lung to the chest wall, so that the bacilli, though numbered by the million, lie embedded in natural prison vaults, almost effectually shut off from again invading the rest of the system.

Among the records of arrested phthisis in this rarefied atmosphere, we Colorado physicians have all seen this natural arrest. In fact, this fibroid process is so evidently Nature's chief reliance in all successful, as well as all fatal cases, that we are led to ask—how can arrest after softening of lung tissue occur without the aid of this natural method? Why, then, since the character of auscultation sounds, and the method of healing caused by mild reactions to tuberculin are so similar to the effects of the fibroid process, only more accurate, why, I ask, should we go outside of natural causes to explain the curative process of Koch's lymph? It is entirely unnecessary. The lack of understanding of this matter is so queerly shown even by men of high repute.

Dr. Bristowe, who opened the late discussion of Koch's method in the Metropolitan Counties Branch of the British Medical Association, scouted at the idea that the bacilli were not killed but simply imprisoned "in an excess of inflammatory products," and Dr. Hector Mackenzie, equally antagonistic in his remarks, claimed that "Koch had led us to suppose that he had himself fully tested this wonderful remedy of his, that he had found that it prevented the growth of the bacilli in the test tube," etc. Dr. S. K. Jackson, of Norfolk, Va., in his late article on Tuberculin, read before the Section of Practice at the May meeting of the A. M. A., in Washiug-

ton, entered into a lengthy argument to show that the bacilli *in situ* are killed by the introduced ptomaines of artificially cultivated bacilli, in accordance with a law which he had some time ago and several times since announced that "no organism can live in its own excreta." The test tube has nothing to do with a natural process like that we are discussing, and as for "poisoning" the bacilli in possession of the battle ground in the lungs, by their ptomaines introduced into the blood hypodermically, I am myself inclined to believe it would be disastrous to the human body, or to any other body, to do such a thing. It does not seem reasonable to me that enough of the ptomaines diluted by the blood would reach the bacilli to poison them. Koch himself says that they are not destroyed. It is now perfectly clear to my mind that *that* is what does occur where Koch speaks of the "imprisonment of the bacilli" in inflammatory tissue, provided that *inflammation* is the proper term to use. But I am led to believe that Koch made a great mistake when he put it before the world that it was the "necrosis" (death) of the affected tissue which was effected, or ever desired to be effected. No, to kill the part, in order to destroy the enemy contained therein, would be such an aggravation, or rather perversion of the splendid healing process at the bottom of his discovery, that no one could gain an advantage from so doing, unless it would be Prof. Virchow, with his twenty-six post-mortems on bodies defunct after tuberculin treatment. The renewal and healing of given tissue affected is not to be brought about by the death (necrosis) of that tissue, which means its extinction. It is not necrosis that takes place or is desired, but a stenosis, through the substitution of new material or the quickened action of Nature's fibroid process, in answer to a local demand. If it were not for an unusual cause, which is the tuberculin in the blood, nothing out of the ordinary would happen. But that which happens is unusual. Here I am led to a confession of faith, which is sufficiently strong to support me in the further use of tuberculin in my practice, though every other physician in America should pronounce against it.

It is a beautiful idea, abundantly verified as the law of Nature in her warfare with disease, that every living tissue is endowed with a certain power of protection against injury, and repair for the same. This power is inherent in, and manifested in harmony with, the activity of the *life principle*. So an acute injury of the delicate lung tissue, where the circulation of blood is five times as rapid as in the capillaries of the service of the body, must result in a correspondingly greater systemic disturbance, and local demand for repair. Therefore, when an unused, poorly ventilated, catarrhally affected portion of lung becomes the congenial and fruitful abode of man's greatest

enemy—the bacilli of tubercle—I believe the call is not unheeded by this independent thought of nature. The resources of the whole system are called upon to aid in the burning out of the enemy by combustion, drowning or washing him out in the rivers of catarrh, or burying him beneath or behind the ever encroaching fibroid battlements. Where else will we find this protective influence more acute than at that point, especially in the lung, where the bacilli are lodged, and already surrounded by *these sensitive, protective elements*? It is not unreasonable to believe that the fibroid tissue which surrounds tubercular spots or ulcerations, and whose chief function and tendency is contraction, should be unusually susceptible to the ptomaines or juice of the bacilli, were these poisons to find their way there through the general circulation. I believe that this is the case, for I have several times verified the contraction of fibroid elements in affected lung tissue under the special stimulation of tuberculin.

I know I shall be deemed delinquent in this article if I do not mention the action of the Philadelphia Commission and the Johns Hopkins College Hospital, in discontinuing the use of tuberculin because they were disappointed with their results.

As to the Philadelphia physicians, whom I highly esteem, I wish to say this: They were scrupulously following Prof. Koch's directions as to *dose and rules of confinement*. I am not. The character of the cases chosen at both the above trials were serious enough, notwithstanding a lurking suspicion in my own mind that had they properly tried stethoscopic percussion in some of their cases, "with tubular breathing and moist crackling râles at an apex," they would have detected excavations *before the treatment* instead of referring an advance in disease to the tuberculin injections. Of course, the contraction of affected tissues around a softened spot makes a small pre-existing cavity more evident.

The Johns Hopkins College Hospital failure is not to be wondered at. They could not surely have expected to have a miracle performed; for had they started out to damn the Koch treatment they could not have done so more effectually than by selecting such a bad lot of cases, housing them in an hospital, and giving them such large doses of tuberculin. Look at the list of the first eleven cases reported. Five of them with both lungs considerably affected; seven with large cavities, and the others with softenings commenced or going on, *i. e.*, according to the physical signs noted in the first report. Had these cases been set loose in the country during the time of the Koch treatment, and reached the maximum of 4 mg. instead of 12 to 20, they would probably have had enough for their needs. I cannot see that the essential precautions men-

tioned in this paper have been taken in any of the experiments thus far reported in the journals. The nearest approach to their observance, which have furnished equally favorable results to my own, have been by Dr. Karl von Ruck, of Asheville, N. C. I was very glad to see from his late paper in the *Medical Record* that he had been working on much the same line as I had. I do not notice in his reports the extravagant general and febrile reactions so grossly exaggerated in newspaper reports of certain so called "Koch hospitals."

CONCLUSIONS.

The following conclusions, however poorly elaborated in the body of this report, seem to me to be warranted at this stage of our investigations.

1. Tuberculin furnishes a natural method of cure, to be classed with stimulants, hypophosphites, exercise, high altitudes and cold, dry air; yet it is too powerful to be indiscriminately used, and the proportion of consumptives for whom its use would be advantageous remains to be determined.

2. It is unreasonable to expect that tuberculin will be useful in sepsis, or any poisonous blood state other than tuberculosis.

3. Use tuberculin not as a substitute, but as an aid to climate, and other natural methods of cure—proper food, hygienic surroundings, mountain climbing, etc. Especially are high altitudes and exercise indicated, if otherwise advisable, because they favor the ventilation of lung tissue, which is necessary in giving tuberculin.

4. Seek only local reactions in the affected tissues. A high or prolonged febrile reaction is to be avoided, if possible. Use the minimum dose that will accomplish this purpose, and it is preferable to let at least a day elapse between a subsidence of one reaction and the possible creation of another. Remember that an increase from $\frac{1}{4}$ to $\frac{1}{2}$ of a mg. may be as great for a case already reacting to the smaller dose as an increase from 30 to 40 mg. in a case that is far advanced in the treatment.

5. The lack of ventilation in a lung, whether caused by tuberculin already used or pre-existing, is a decided contra-indication to pushing the treatment, *i. e.*, according to this deficiency and the febrile state.

6. The test for the proper ventilation of a tubercular or fibro tubercular lung is to be found in the comparison of the spirometrical record with the bilateral measurements of the chest and with available physical signs. A fair way to express deficient ventilation is to say, if the normal spirometrical record for the height is abridged one-half, and the movements of the two sides are as one to two, then there is sufficient lack of ventilation in the weaker lung for exercising extra caution as to using tuberculin at all. There is

either too much elastic tissue already there, or the bacilli, if loosened by tuberculin, may not be expelled.

7. The stage of the lung disease has not so much to do with the question of using tuberculin at all, as has its extent and locality, the febrile course and the ventilation of the affected lung. If possible, have an average daily range of temperature of less than two degrees F. upon which to proceed, and the patient able to be much of the time in the open air.

8. The diagnostic value of small hypodermics of tuberculin is shown with or without febrile reaction in the appearance on auscultation at suspected or affected spots in the lung substance, of a more or less decided *roughening of a previously existing broncho vesicular respiration*; or a *high pitched, rude breathing* where before only a feeble respiration was noticed.

9. With the appearance of any unfavorable physical signs during the course of tuberculin treatment, such as a clogged up section of lung, or scattered moist râles suspicious of softening, I think it would be well to intermit injections of tuberculin and substitute those of iodine for a while, or to give temporarily syrup hydro-iodic acid compound, or to use inunctions of ointment of mercury over the affected lung, until a return to the use of tuberculin is quite safe.

10. As to permanence of effects produced by tuberculin injections, there is to me no apparent reason for expecting any more lasting results than from any other agency which will accomplish as much. I do not see any reason why bacilli should not appear again in the sputum after their cessation under tuberculin treatment, as after their cessation under climatic change or the double chloride of gold injections. It is quite probable that the effect of tuberculin is temporary. We need not look for a guaranteed immunity from lung tuberculosis except under such other conditions of healthful living as would insure it.

11. In fine, tuberculin is not a remedy to be chosen for the great majority of pulmonary consumptives in preference to a proper change of life and climate, for it does not equal the latter; but with such a change, it is an important adjuvant to the cure of a large selected class of tubercular lung diseases.

Denver, Col., June 15, 1891.

BEQUESTS TO MEDICAL CHARITIES.—By the will of the late Mr. John T. Farish, who died recently in New York, charitable bequests were made to St. Luke's Hospital, \$50,000; Home for Incurables, \$50,000; New York Cancer Hospital, \$25,000; Hospital for Ruptured and Crippled, Nursery and Child's Hospital, House of Rest for Consumptives, and Manhattan Eye and Ear Hospital, each \$10,000.

LOCATING THE BALL IN A CASE OF GUNSHOT WOUND IN THE CERVICAL REGION.

Read before the Chicago Pathological Society, June 8, 1891.

BY J. J. M. ANGEAR, B.Sc., M.A., M.D.,

PROFESSOR OF PHYSIOLOGY, NERVOUS AND MENTAL DISEASES IN THE COLLEGE OF PHYSICIANS AND SURGEONS, KEOKUK, IOWA, AND PROFESSOR OF PHYSIOLOGY AND PATHOLOGY IN THE U. S. DENTAL COLLEGE, CHICAGO, ILL.

Twenty-second day of August, 1889, I was summoned to see Mr. W., in the south-east part of Kansas, under the care of Dr. D. W. King, of Wier City, Kansas, whose history I learned as follows: Mr. W. was born in Henry County, Ill.; was 33 years old; had lived in Cherokee County, Kansas, nineteen years; married, had no children.

On the 11th day of May, with others, he was out hunting, and was accidentally shot in the neck by a glancing shot, with a 22 caliber rifle ball. The manner in which it occurred will be better understood by referring to the diagram.

The tree, C, was in a field. The line A B represents a hedge which divides the field from the road. E and F represent two men who fired at a bird on a branch of the tree, C. A ball from one of the two men's rifles E or F, struck the branch on which the bird was, and glanced and struck Mr. W., at D, a distance of 105 feet, who at the time was intently watching for game in the hedge, carrying his gun in his hands, cocked. His body was leaning forward, head still further forward, and thrown toward the right. The ball struck him a little back and inward of the point of the shoulder. He fell on his face across his gun. He experienced no pain, but could not breathe. He supposed that his gun had gone off and the rebound had struck him in his stomach, and had "knocked his breath out." It was some time before he could breathe; there was no hæmorrhage.

Dr. King could not follow the direction of the ball with the probe, because the probe could be more readily passed between the muscles. And it was impossible to put the body in the exact position that it was in when shot.

His temperature rose to $105\frac{1}{2}^{\circ}$, pulse 110 and remained so for one week, when temperature fell to $103\frac{1}{2}^{\circ}$, and the pulse to 100. The temperature remained at $103\frac{1}{2}^{\circ}$ for eight weeks, when it fell to normal and remained so for two days only.

For the first four weeks he experienced excruciating pain in his shoulders. Dr. J. D. Griffith, of Kansas City, was called May 19, 1889. He operated, with the view of removing the ball, by cutting down upon the spinal column, and found the lammæ of the sixth cervical vertebra badly fractured and slightly pressing on the cord, but no hole in the lamina. He removed the spinous process of the sixth cervical vertebra with the bone forceps, and with a large trephine removed the lammæ and picked out the fragments of bone. The dura mater was badly torn; he removed the torn portions with the scissors. The cord was not wounded nor contused. He did not find the ball so he closed the wound, which healed by granulation, readily. The next day severe nervous rigors set in, and spasmodic contractions of the muscles, akin to rigor mortis (tonic spasm). They continued for two weeks, in fact have never left him entirely. Drs. Agnew, Wyeth, Gregory and myself had been consulted by letter. Prognosis given was unfavorable.

I saw him August 23, 1889, three months and twelve days after the accident, and found him as follows: Mind as clear as ever, paralyzed below the neck on both sides, except the deltoids. He could lift his arms and move his little fingers slightly. His face was dark with fine red spots or points, such as we sometimes see in cases of epilepsy. Breathes well while lying down, but with difficulty when sitting up. The muscles of the back of his neck are paralyzed, and his head drops forward upon his breast; when his head is brought forward far enough so that the centre of gravity of his head falls in front of its support then he stops breathing, becomes entirely unconscious; by lifting his head and putting him on his back, so that his neck is straight, in a short time he breathes, becomes conscious. He looked around in a bewildered manner and asked, What is the matter? Where have I been? How long was it?

With ease and without pain he is able to move his head in every direction, except backward. No difficulty in moving his tongue; voice and eyes are normal, so are all of his special senses except feeling. At first he had to be cautious in swallowing else the material which he attempted to swallow would pass into the larynx. At present there is a great improvement in this regard. May say that deglutition is normal.

Rate of respiration, at first ran down in proportion, as the pulse ran up. This has improved, but the rate of respiration at present is not quite in due proportion to the pulse-rate. The pulse runs down to 40 per minute when the bladder is washed out.

The urine had to be drawn off every six hours, and would draw off from a quart to one-half gallon each time for the first eight weeks. Since

that time it has passed off of its own accord, but not unconsciously. There is a desire to urinate. He has but little control over the bladder. He can hold the urine for a very limited time, a few seconds only.

At first the bowels moved without cathartics, but not at present. He has a little better control over the rectum than over the bladder. The inferior extremities feel as if asleep, but better than they were. Not much of formication. Sensation exists all over the body, but very low, not able to recognize two prints of the æsthesiometer anywhere below the point of injury; but he can tell when and where he is touched or pricked, and says he could touch any part of his body he may be asked to, were he able to move his hands and arms.

When the æsthesiometer is put across the limb, instead of recognizing the two points, he says it seems to him as if something were pressing upon or across the limb.

The heart and lungs are normal. Reflexes of the superior flexor muscles are present, but not the extensors. Did not test the knee-jerk. Could not get any ankle clonus. Tickling of the soles caused no contractions, but he said he felt it. No pain in his head except soon after the operation, and then in the occiput.

There is a sudden contraction of all the flexors of the body from the slightest irritation, as the movement of the bed clothes, or a draft of air strikes him. He will draw up his feet and legs, draw his hands up under his chin, his head forward, and bend his trunk forward; thus the body gets into a ball, as nearly as possible. No apparent atrophy of any of the muscles. Priapism just making its appearance very slightly. There is a large bed sore over the sacrum, which was started by leaving the bed-pan under him too long at one time.

The first thing is to locate the ball, if possible, then to determine a course of treatment, if anything can be done.

The branch of the tree that was struck instead of the bird, and from which the ball glanced, is about eight feet from the ground. The ground where Mr. W. was standing when shot is about eighteen inches below the foot of the tree. Hence the total elevation from which the ball came is nine and one-half feet. Mr. W. is five feet seven and one-half inches in height, and was stooping, and was shot a little above the point of his shoulder, hence the ball struck him about five feet above the ground. This height, subtracted from the total elevation, is about four feet six inches. Therefore the ball, in reaching its victim, had a descent of about four and one-half feet in 105 feet, thus represented.

Practically the elevation was nothing in comparison to the distance—a little over one-half inch (.514) in a foot.

The inclination of the body forward and the head forward and to the right, more than counterbalanced the elevation from which the ball came. Practically it was as if he were standing erect and the ball came from below and from his left and behind him, hence the ball travelled upward and forward, striking the left lamina. This surface looks backward, downward and outward, which deflected the ball a little backward and upward. The ball must be above the point where it struck the spinal column. If the ball came with sufficient force to penetrate this lamina, it is to be found above the point of entrance into the canal. The distance it will travel upward in the spinal canal will depend upon the momentum that the ball had at the time of its entrance into the canal. This we have no data by which to make any calculation.

Our mathematics, or mechanics, tell us the ball is up above the point of entrance. There was but one wound, hence we know that the ball is in the neck. Either in the spinal canal or it had fractured the lamina and lodged just outside the spinal column. If this is to be told it must be told by symptoms and not by mechanics.

The nervous center for respiration extends from the upper part of the medulla oblongata down to the third or fourth pair of cervical nerves. There being no difficulty in breathing when the head is in a normal position, hence that part of the cord was not damaged.

The spinal accessory arises as low down as the fourth pair of cervical nerves; was not interfered with in its function, because voice was normal and he was able to rotate his head.

The brachial plexus arise a part above and a part below the fifth cervical vertebra. The circumflex animates, the deltoid and the ulner goes to the little finger; both of these were less affected than any other part of the brachial plexus. He could with difficulty lift his arm and slightly move his little finger. These all tell us that the ball is as high and no higher than the fifth cervical vertebra.

We must remember that the dura mater of the cord is not attached to the spinal canal, but there is a space between the cord and the dura, as well as between the walls of the canal and the dura, therefore we are able to introduce a probe between the cord and the dura or between the dura and the walls of the canal for two or three inches with impunity; for this reason we wondered why in the operation the ball was not found, and we were told that the lamina was fractured; but there was no hole through which the ball entered the canal. We began to doubt seriously that the ball was in the spinal canal. At this vital point, symptomatology is too cloudy to aid us to

4 ft.

35 yards, or 105 feet.

dispel the doubts. If there are any symptoms or evidence of cut, lacerated or compressed cord, they were so completely covered by the symptoms of general meningitis and myelitis that they could not be recognized.

We gave our attention to the external parts of the neck in the vicinity of the fifth vertebra. We found a very tender spot opposite the transverse process of the fifth vertebra on the left side. If this was the ball, it was playing no part in the present nervous disturbance, and not being positive that it was the ball, he refused to have an exploratory incision made, saying he had been cut enough to no purpose. We soon came to the conclusion that the meningitis and myelitis had almost destroyed the cord. Had the ball destroyed the cord there would have been priapism from the beginning; but as it is, it is but just beginning, and it is to be taken as evidence that secondary degeneration has taken place, and regeneration of nerve substance under such circumstances, is not known to occur. Muscular atrophy follows destruction of the cord and there is no evidence of atrophy at present. Spasmodic paralysis is evidence of secondary degeneration.

The high temperature which existed for the first eight weeks is evidence of meningitis, and not injury of the substance of the cord. The contractions of the flexor muscles came from the myelitis. Thus far the degeneration is of the descending variety alone. Had there been any of the ascending variety, he would have died of asphyxia before this.

We have decided that the ball is up as high as the fifth vertebra. If we operate we must remove the transverse process and laminae of the fifth vertebra. The process prominens, the spinous process and laminae of the sixth vertebra are gone, and now to remove the transverse process and laminae of the fifth vertebra, is to remove a large portion of the support to the head, and would be, at least, a mutilation which demands serious consideration, and not to be perpetrated without strong hope of bringing about such relief as to undoubtedly compensate for the great loss.

Should we cut down, find the ball and remove it, it would not remove the damage already done to the membranes and cord, nor would it put a stop to the chronic meningitis and myelitis, nor would it arrest the degeneration that is going on. It would aggravate all these pathological conditions, and simply hasten the final end.

This array of facts compelled us to abandon all thought of operating. We had an apparatus made to hold his head in position, with the hope that it might enable him to sit up, and even to be taken out of doors, and thus maintain his general health, give the bed-sore an opportunity to heal, aid the bladder in getting rid of the

urine, which is becoming ammoniacal, and thereby lessen his suffering and prolong his days. With it he was able to sit up five or six hours at a time, but could not wear it all the time, it made him "so tired."

Figure 1.

Dr. King wrote me in substance as follows: "The cystitis became very bad, though the bladder was well attended to, was washed with various antiseptic washes; the urine became so offensive that it was very sickening to wash out the bladder. The priapism became very troublesome, also the tonic spasms of all the flexors. The muscular atrophy was very great before he died."

He died September 5, 1890, one year, three months and twenty-four days after the accident. Ten days previous to his death he had been passing from his bladder a material resembling prune juice in color and consistency. Pulse full and strong, 120 per minute. Temperature 103°, respiration 20, with stertorous breathing.

Post-mortem three hours after death. A deposit had been thrown out over the cord where the lamina had been removed. The ball struck the lamina of the sixth cervical vertebra and deflected upwards, and penetrated the dura mater on the right side of the cord, at a point corresponding to the middle of the fifth cervical vertebra, where it now remains. The fourth, fifth and sixth pair of cervical nerves, for a distance of an inch from the cord, showed traces of atrophy, but the brachial plexus was normal.

The walls of the bladder were from three-fourths to an inch in thickness, and resembled the inside of a gizzard. Numerous bands of a gelatinous

substance, black and gritty, formed an artistic network over its surface. It was extremely attractive to the eye, but disagreeable to the nose.

The same prune juice-like material was in the ureters and kidneys. Numerous calculi were

found in them. The kidneys were enormously hypertrophied, and especially the right one. The

liver was enlarged. The stomach, heart and lungs were normal. It is very evident that death was caused by uræmia. The cystitis was caused from the injury from the cord. Nephritis was set up by the inflammation of the bladder. The nephritis caused the uræmia.

Figure 4.

Microscopic examination of the cord just below the ball: No. 1, shows the cord as a whole. All normal appearances of the cord are destroyed by the myelitis.

No. 2, a lateral portion more highly magnified, showing the hypertrophied neuroglia and blood-vessels, but it fails to bring out any motor cells or nerve tubules.

No. 3 shows the thickening of the membranes, the result of the meningitis.

Fig. 4. Fifth cervical vertebra, showing the ball between the cord and membranes.

A Case of Hermaphroditism.

Prof. Polailon has recently¹ reported an interesting case of hermaphroditism. The patient, Marie P., æt. 25, was referred to him July 1887, for the purpose of having an operation made, because of absence of the vagina. The young woman had never menstruated, nor had she had any periodical sickness, nor congestion, nor hæmorrhage of an organ taking the place of menstruation.

The external genital organs were well formed. The mons veneris, the labia majora, and labia minora were normal. The clitoris was of ordinary dimensions and appearance. Below it the meatus urinarius occupied its usual place. But behind the fossa navicularis the vagina was represented by a depression scarcely two centimeters in depth. Above this depression the most careful examination failed to reveal the slightest trace of a uterus. At the level of the external inguinal ring on each side there was a swelling resembling a bubonocoele. Each swelling contained a hard, ovoid, mobile body giving a peculiar sensation on pressure. On coughing there was only a slight propulsion of the intestine behind or beside these organs. She had never observed that these organs became more voluminous or more sensitive at certain times. In physique she had all the characteristics of femininity. In stature a little above the average, her pel-

¹ Soc. Obst. et Gyn. May 14, 1891.

vis was large, and hips prominent. Her breasts were well developed. Her skin was soft and fine, and a moderately thick panniculus adiposus spread over the trunk, and rounded out the limbs. There was no trace of beard on the upper lip or chin; the larynx was not prominent and the voice had the feminine timbre. Finally, her feelings and tastes were those of a woman. As the result of the examination an operation was declined. Not disheartened she gave herself up to a life of shame, and her lovers soon formed a vagina as well as surgery could have done it. At the end of a year the vaginal depression had acquired a depth of 5 to 6 cm. and later it measured 7 to 8 cm. In October, 1890, she was admitted to Polaillon's service at the Pitié sick with a grave albuminuria. At this time the vagina was as long as an index finger and admitted a cusco speculum. The skin folded in between the bladder and rectum had taken the rosy tint and softness of a mucous membrane. The two small tumors had not changed any.

She died December 17, and the autopsy gave the following results:

The peritoneum covered the bladder, which was normal, and was then reflected upon the rectum, forming between the two organs a cul-de-sac. On the sides the peritoneum extended to the iliac fossæ, and formed no folds which could be taken for broad ligaments. But it formed two antero-posterior folds, projecting slightly, to which we shall again refer. The whole pelvic peritoneum was lined with a layer of smooth muscular fibres, disposed in interlacing bundles. On dissecting off the peritoneum there was no trace of ovaries or tubes found beneath it. Nor was there a uterus. But in the place where the uterus should have been found, below the recto-vesical cul-de-sac, there was a thickening of the tissues, forming a lump about the size of a bean. This lump was situated in the median line, a little above and in front of the bottom of the artificial vagina. It was so small that it was impossible to detect by vaginal touch. From each side of the lump in the median line, a cord passed obliquely forward, outwardly and downwardly, ending in the bodies contained in the inguinal hernias. These two cords were each composed of a conduit resembling a *vas deferens*, and of vessels encircling it. The inguinal tumors each contained an ovoid organ, white in color, with a smooth surface, and enclosed in a serous cavity analogous to a *tunica vaginalis*. The form and disposition of this organ differed slightly on the two sides.

On the left the large end of the ovoid was situated high in the inguinal canal; the small end was disposed in the form of a crinkled body which adhered to the inguinal ring, and which received the left cord. The serous tunic surrounded only the upper end of the organ, extending into the inguinal canal, but without communicating with the peritoneum.

On the right the organ was more rounded, shorter, more regular, and better projected from the inguinal canal. It had clearly the aspect of a testicle. It was surrounded by a vaginal tunic which adhered to its vaginal portion as far as the level of an epididymus thickening from which the right cord came out.

On each side a vasculaire bundle, which represented the spermatic artery and its veins, descended below the peritoneum to supply the inguinal organs, which were evidently testicles.

On a transverse section of the right gland there was seen, at the periphery, the *tunica albuginea*, and at the center, characteristic testicular substance. In a longitudinal section of the left gland there was likewise found the *albuginea* at the periphery, testicular substance in the center, and at the lower portion of the gland, the body of Hygmore, a rudimentary epididymis.

The histological examination, made in M. Cornil's laboratory, showed in the testicular substance seminiferous tubes, with thick, sclerosed walls, filled with atrophied epithelial cells. They were then two male

organs, but atrophied, sclerosed organs, and without physiological activity.

The attention of the histologists was also directed to the small retro-vesical lump, whence emerged the deferent canals. The question to be settled was whether it was a rudimentary uterus or a vestige of prostate. A very minute examination revealed only muscular fibers extending in various directions, but no cavity lined with epithelium, and no glandular formation. It was therefore neither a uterus nor a prostate, but simply a thickening of sub-peritoneal muscular tissue.

The neck of the bladder was then searched for the vestige of a prostate. At this point there was found a rounded organ which embraced the origin urethra, and resembled a small prostate. Microscopic sections showed that this organ was formed of muscular bundles, the interstices of which contained glandular formations. It was, then, a rudimentary prostate, but a prostate without prostatic utricle, and without ejaculatory canals. The *vesiculæ seminales*, moreover, were wanting entirely. On each side of the vulvar orifice were two very distinct vulvo-vaginal glands, with their ducts opening at the vulva.

On continuing the autopsy, there was found an interstitial nephritis of both kidneys, a congested and inflamed spleen, a well developed pancreas, and a liver of normal appearance. There were serous effusions in the pleural cavities and pericardium, and the heart presented a slight degree of endocarditis. A most striking feature of the autopsy was the small volume of the arch of the aorta, which could not admit the little finger into its cavity.

The genital anomaly classes this individual among the false hermaphrodites of the androgynous variety. In fact, Marie P. was a man. But the presence and very advanced evolution of the testicles had not impressed on the organism the characters of the male sex, or only some of these characters. On the other hand, a consideration only of the appearances and the external forms indicated a woman affected with an absence or imperforation of the vagina.

From the surgical standpoint, there was no indication for the creation of an artificial vagina, for there was no uterus, nor upper cavity, forming a vaginal vestige, toward which a route might be cut. Under these conditions it is the rule to withhold operation. In fact, in opening up the recto-vesical space to a certain extent, there is obtained only a limited conduit, with bleeding surfaces, which continually tend to reunite by cicatrization. The result obtained can not be kept because of the cicatricial retraction. But the observation of this patient shows that in similar cases a vaginal conduit can be slowly formed by pushing in the skin between the bladder and rectum with a large mandrel. In this way the bladder could be separated from the rectum, the vulvar mucous membrane pushed into a cul-de-sac, and a sort of vagina created, which could be subsequently completed and maintained by sexual approaches—*Journal de Médecine de Paris*.

THE COMBINATION of cocaine and antipyrin is said to produce a more lasting and complete anæsthesia than cocaine used alone. Dr. Martin (*Med. News*) suggests, for powerful local anæsthetic effect on the gum and sensitive dentine, the following solution:

Cocaine Hydrochlorate crystals, $\frac{3}{4}$ gr.

Antipyrin, 6 grs.

Water, 16 drops.

Our own observation inclines us to prefer 2 grains acetanilid to the antipyrin.—*New Remedies*.

CHICAGO, ILLINOIS.

All members of the Association should send their Annual *Dues* to the *Treasurer*, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

BY-LAW IV.—THE PUBLICATION OF PAPERS AND
REPORTS.

No report or other paper shall be entitled to publication in the volume for the year in which it shall be presented to the Association, unless it be placed in the hands of the Board of Trustees on or before the first day of July. It must also be so prepared as to require no material alteration or addition at the hands of its author.

Authors of papers are required to return their proofs within two weeks after their reception; otherwise they will be passed over and omitted from the volume.

Every paper received by this Association and ordered to be published, and all plates or other means of illustration, shall be considered the exclusive property of the Association, and shall be published and sold for the exclusive benefit of the Association.

The Board of Trustees shall have full discretionary power to omit from the published *Transactions*, in part or in whole, any paper that may be referred to it by the Association, or either of the Sections, unless specially instructed to the contrary by vote of the Association.

THE BACTERIOLOGY OF THE UTERINE CAVITY
IN ENDOMETRITIS.

Since the observations of Noeggerath, increased attention has been devoted to infections of the genital tract of women. Whilst it must be confessed that the views of Noeggerath present many striking facts in their support, yet it cannot be denied that too much stress is laid upon one inficiens, namely: the gonococcus, and too little upon other pathogenic forms, that possibly play a most important rôle in these inflammations. Our attention is again called to this subject by Alexander Brandt, of Slarjansky's Clinic, St. Petersburg, (*Centralblatt für Gynäkologie*, June 20, 1891), in an important preliminary communication.

It consists of a careful bacteriological examination of the uterine cavity in twenty-five cases of endometritis, presenting the following varieties: E. hæmorrhagica, eleven; E. catarrhalés chronica, nine; E. gonorrhœica, four, and E. septica, one. Apparently every effort was made to obtain the contents of the uterine cavity free from admixture with the secretions of the cervical canal, the latter being thoroughly cleansed before going beyond the internal os. The uterine

cavity was then scraped with a Volkmann spoon and the removed portions examined microscopically, and cultivations were made upon solid media. By cultivation, twenty-two of the twenty-five cases showed the presence of microorganisms. In two cases the streptococcus pyogenes were identified. A pure culture of this germ was obtained from the case of septic endometritis; in two cases of hæmorrhagic and one case of catarrhal endometritis, the staphylococcus pyogenes aureus were found; in two cases, alone, and in one, associated, with the staphylococcus pyogenes albus. This latter germ was found, alone, in two cases of the hæmorrhagic form.

Pure cultures of these germs were made according to Koch's method, the results showing that in seven cases, or 31 per cent., pathogenic microorganisms were found. Inoculation experiments were performed with the pure cultures, demonstrating that in each instance the streptococci and staphylococci retained their full virulence.

It will be readily admitted that the mere association of a lesion and the presence of a germ, does not indicate a pathological nexus; indeed if the latter is admitted, it does not follow that the disease is the product of the germ. Still, if we put these questions aside, for the moment, and come to the treatment, we will find but few surgeons, who do not believe in the prompt and thorough removal of the suppurative bacteria. When present upon a diseased membrane, whether primary or secondary in their operation, they can but do harm. Such being the case, we conclude that the observations of Brandt, in accord as they are with older researches, confirm the value of antiseptics in the treatment of the uterine mucosa, as indeed of all other mucous membranes.

EARLY PREPARATION FOR THE SECTION
WORK.

The true foundation of the scientific work of the American Medical Association lies in the Section. It is there that the real work is done, and the chief interest of members is found. The general sessions may profitably discuss the broad questions of medical education, ethics and legislation which alike affect all, and in which all are interested.

To our mind a continued growth, and increase

in the usefulness of the Association, largely depends upon a strengthening of the work done in the Sections. This, if accomplished at all, must be largely through the efforts and activity of the Section officers. There now remain eleven months before the next annual meeting at Detroit; it is none too soon to begin preparation for that meeting. We feel that we cannot urge this point too strongly, as we know that the Section work is commonly left to the two or three months preceding the date of meeting. This is all wrong, as it leaves too little time for the preparation of papers and discussions. The result is that the programme is often hurriedly made up and badly arranged, to the serious detriment of scientific work.

It is to be hoped that work will begin now for the next meeting. Section officers should begin correspondence with contributors, discussions should be arranged, and so far as possible the work mapped out. It will be found that there is none too much time for the preparation of a clean cut, well arranged programme.

We would especially call attention to the value of set topics for certain sessions, upon which one or two papers are prepared, and then several members are designated to take part in the discussion. This plan has worked well in many foreign societies, and has to some extent been adopted in our Association. Nothing is more attractive to a writer than to know that his paper will be intelligently discussed, and nothing contributes more to that end than a well arranged programme and precision in the work of the Section.

An effort will be made at the Detroit meeting to secure verbatim reports of the discussions.

NATURE'S FOOD.

Nature's food for the infant is the milk of the mother. That it is the best food for the infant is accepted by all. But this means that it is the best food for the healthy infant. Nature has not provided a food for the sick child, particularly not for the child suffering from bowel disorders. Statistics abundantly prove that a large majority of the infants dying from the bowel disorders of summer are to be found among those who have been deprived more or less completely of their natural nourishment. From this undisputed fact

it has been too often inferred that the proper food for the child affected with summer complaint is mother's milk, or in its absence that substitute which may be supposed most closely to resemble it. This is clearly a *non sequitur*. The conclusion should have been that the natural method of feeding the infant is a most excellent prophylactic against bowel trouble.

But to go farther, and to assume that a prophylactic measure will be a curative measure is clearly unwarranted. Vaccination will not cure varicella.

The various efforts which have been made and are being made to imitate mother's milk, in its physical, chemical, and biological aspect, are worthy of the highest respect, but even should they reach an ideal conclusion, it will be to supply a food for the healthy baby, and not for the sick one. When sterilized milk was offered to the profession its advent was hailed by many as an important step forward in the feeding of sick babies, but its shortcomings are now becoming apparent, and are attracting the attention of medical writers.

The various abnormal fermentations which occur in the intestinal tract of the infant suffering with bowel trouble and which can be maintained by a milk preparation of one kind, can be maintained by a milk preparation of another kind. A microorganism which can grow in one milk food, can grow in any other milk food. To sterilize milk, and then introduce it into a nest of bacteria is a trifle illogical. And this illogical procedure has had its origin in the effort to imitate Nature's food.

If now, instead of stating with an hypothesis, the ground had been cleared of fetiches, and attention directed to the real problem, no doubt a much more tenable position would now be held on the subject of the proper food for a diarrhœal baby. The starting point for observation is a simple one: Abandon all hypotheses, study the conditions present in the child, and adapt the food to those conditions, on principles which shall be comprehensive.

IMPURE ICE.

The heated term is upon us, and with the season comes the crave for cooling drinks. The carbonated drinks furnished by the shops are

usually healthful, but too frequently there is a temptation to indulge freely in the water of melted ice. This, when gathered from impure sources, is just as unfit for drinking and culinary purposes as any other stagnant water. Many have supposed that the freezing process effectually eliminates all impurities. That such is not the case is abundantly proven by the tracing of cases and epidemics of enteric diseases to the use of impure ice water. The germs of typhoid are not destroyed by the freezing of the water in which they are present. In urban districts where ice is manufactured from distilled water it should be given the preference for all household purposes. It being remembered that boiling the water destroys the harmful microbes, and freezing does not make them uninfecious.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Early in July the summer Medical Corps of the Board of Health commenced their two months' service in the tenement house districts of the city. There are fifty of these physicians, one for each district, and it is their duty to make house to house visits among the poor for eight hours daily; reporting twice a week at Sanitary Headquarters, to Dr. Moreau Morris, one of the most experienced officers of the Board of Health, who has special charge of this department of its work. They are required to seek out and treat all cases of disease, especially among children, which are not already being cared for by private or dispensary physicians, to give advice in regard to the care of infants and young children in hot weather, and in regard to sanitary matters in general, and to promptly report all nuisances and all cases of contagious disease met with. They distribute in every household copies of the Board of Health's "Rules for the Care of Infants," printed in French, German and Italian, as well as English, and are also provided with free tickets for the salt water excursions of the St. John's Guild Floating Hospital, which they furnish to all suitable cases. The city appropriates \$10,000 for carrying on this work, each physician receiving \$200 for his two months' service, and the salaries are certainly well earned, for the duty is a most laborious one, and the mere physical exertion of climbing to the top floor of one five-story tenement house after another, in the hot weather, is no trifling matter.

There can be no question that this house to house service is of very considerable importance in keeping down to some extent the infant mortality which is, unfortunately, always so extremely large in the summer months in a great city like New York; and the special usefulness

of it is no doubt to be found in the fact that by this means many cases of diarrhoeal disease are discovered and treated in their incipency, which would otherwise be permitted to run on without interference until all medical aid would be useless. The extent of the work can be readily seen from the statistics of the summer corps of physicians in the season of 1890, which are as follows: Number of tenement houses visited, 40,364; families visited, 321,012; sick cases treated; minor nuisances abated by personal effort, 5,413; complaints of nuisances forwarded, 551; circulars in regard to the care of infants distributed, 51,784; tickets to the St. John's Guild floating hospital excursions, 16,627. In the city of Brooklyn the same plan of summer service has of late years been adopted, and there are now some twenty physicians engaged in the work there.

In connection with the saving of infant mortality, it may be mentioned as a matter of interest that one of the large down-town dispensaries (the Eastern), has commenced the preparation, under the supervision of a competent physician, of sterilized milk for the use of the poor of the neighborhood. It is supplied at a low price to those who can afford to pay for it, and gratuitously to those who are unable to do so. It has been claimed by the well-known authority on the subject of milk, Dr. E. F. Brush, that children fed exclusively upon milk that has been devitalized by sterilization are not as efficiently nourished as those fed on unsterilized milk; and the remedy which he would suggest for the poor character of milk so generally in use, is reform in the dairy itself, an important feature of this reform being the spaying of all heifers to be used as milch cows. But, even if Dr. Brush is right, it will be a long time before the milk supply for the poor of our great cities is what it ought to be, and the best milk even is liable to contamination and rapid changes in hot weather. The general sterilization of milk in hot weather at least (granting that his views are correct), would therefore seem to be the lesser of two evils; and, leaving out of the question the matter of possible tubercular infection through unsterilized milk, there would undoubtedly be a decided diminution in the infant mortality from diarrhoeal diseases if the various similar institutions throughout the city would follow the example of the Eastern Dispensary in supplying sterilized milk.

During the early part of July the number of deaths reported in the city, while sufficiently large, indeed, has been considerably smaller than the average for the same period during the last five years, and this is no doubt due in great measure to the unusually cool weather that has prevailed. A very large proportion of all the deaths, however, have been among children under one year, and most of these have been carried off by diarrhoeal diseases. There is always, naturally, a diminution in the number of deaths from respiratory diseases at this season of the year, and there has also lately been a marked falling off in the deaths from contagious and infectious diseases. In one week recently (that ending July 4th) there were only two deaths from typhoid fever reported in the city—a most unusual and gratifying circumstance.

While the eye witnesses of the four executions at Sing

Sing prison on the 7th of July have been bound to secrecy, and no newspaper reporters were permitted to be present, it seems to be perfectly clear that on this occasion the method of electricity proved an unequivocal success, death in each instance being instantaneous and entirely painless. One of the physicians who was present at the execution of Kemmler, and also at Sing Sing, Dr. C. M. Daniels, of Buffalo, has been rather more communicative than the others, and he states that while he never had the slightest doubt that Kemmler's death was instantaneous and painless, the Sing Sing executions were a great improvement over his, being systematic, well planned, and perfectly carried out in every detail. "There was," he says, "no absence of head to direct and control, as at the Kemmler execution. Every man who took part in the execution knew exactly what was expected of him and what responsibility rested on him, and if there had been any blame to place after the executions it could not have been thrown from shoulder to shoulder, as it was after the Kemmler execution."

Dr. A. P. Southwich, the originator of execution by electricity, who was also present at Sing Sing, has expressed himself as completely satisfied with the result. He is reported as saying: "The executions were a success in every way, and there was not the slightest hitch. Electric execution has come to stay. These executions have demonstrated that the method is humane."

The Amenities of Medical Discussion.

To the Editor:—The readers of THE JOURNAL, who are interested in the legal side of their profession may remember an article in the issue for May 2, 1891, on "Medical Cases in the Courts," in which was a paragraph entitled "Cosmetics and Spectacles in Court." They may also have noticed a savage attack on the writer in the issue for June 6, 1891, under the title of "The Optician and Ophthalmology."

It has been said that physicians show more bitterness in their discussions of unsettled questions than members of other professions, and it would seem as if this article tended strongly to prove the statement.

If reference is made to the articles it will probably be admitted by every unprejudiced person that the lawyer made a candid and even tempered statement, while the physician or ophthalmologist, if he prefers so to be styled, made a violent, and uncalled for attack and lost control of himself in the heat of the argument.

The doctor in question, Dr. George M. Gould, goes so far as to say that the article should have been excluded from the pages of a journal caring for scientific medical progress.

Perhaps the editor of THE JOURNAL will be pleased with the snub so felicitously given him, and it might be well for Dr. Gould to send a comprehensive statement of his opinions to all the medical journals of the country, and demand that nothing be admitted which varied from them.

No doubt Dr. Gould's standing in the profession is such that a request of this sort coming from so promi-

nent a gentleman would be most humbly acquiesced in.

A considerable portion of the paragraph is quoted by Dr. Gould for the purpose of heaping contumely upon it, but he seems to be unconscious that it is merely re-statement of the opinion and reasoning of the French Court on the question at issue.

Possibly he intends to ridicule the decision of this court, but those persons who rail at judges do not usually commend themselves to the approbation of the public.

Dr. Gould says that when a layman (referring to the writer) attempts to say anything about medicine he takes the side of ignorance and untruth and makes a mess of what he has to say.

If Dr. Gould will take the trouble to read the article he will probably find out, that the writer did not undertake to give any opinion whatever about medicine but rather about law, and possibly on such subjects he is as well qualified to speak as Dr. Gould.

Nothing was said in regard to the respective merits of the optician and the ophthalmologist in treating weak or diseased conditions of the eye, but the opinion was given that, as a matter of law, the optician, when he furnishes glasses believed to be suitable for a customer, does not violate the medical license laws of this country.

Why the expression of such an opinion, which is entirely within the proper scope of a writer on medical law, should excite such unbounded wrath it is difficult to understand, except on the theory that Dr. Gould is in some way the duly examined, licensed and appointed protector of his profession. The writer did not say or intimate in anyway that the optician knew as much about the eye as an ophthalmologist, nor did he approve even by inference of ignorance on the part of the optician. On the contrary he believes very strongly that the better medical education the optician has the more certainly will he be able to give the right glasses to a customer.

If Dr. Gould means to say that a person selling glasses in an optician's store, after endeavoring to fit them to the needs of the customer, is liable for a breach of the medical license law, he should make such a statement boldly.

The writer expressed the opposite opinion. In either case it is really an opinion about law and not about medicine, and consequently the whole of Dr. Gould's tirade finds no sound basis.

The writer, not having the fear of Dr. Gould before his eyes (in this case no glasses at all are used, the sight being perfect), reiterates his opinion that the optician who sells glasses does not violate the medical license law any more than does a person in the establishment of an artificial limb manufacturer who sells a cork leg to a customer.

If Dr. Gould believes the contrary he should at once get up a test case in his own city of Philadelphia, where there are no doubt numerous opticians who daily sell glasses to customers.

It will, however, be probably a rather disheartening drawback to him to know that he must convert the district attorney to his view before he can make much progress in the effort to root out the opticians.

HENRY A. RILEY, A.B., LL.B., New York.

The Hypodermatic Use of Quinine.

The following communication addressed to a subscriber so fully covers the subcutaneous use of quinine, that he has asked and obtained permission to have the same published.

Dear Doctor:—I take great pleasure in replying to your inquiry in regard to the hypodermatic employment of quinine. I generally use the sulphate, adding dilute sulphuric acid, drop for grain, then water enough to make one syringeful—25 to 30m. Sometimes a drop or two more of the acid is necessary. Five grains is the usual quantity for a syringeful, and in giving larger quantities (I usually give 10 gr.) I repeat the injection. The solution is always made as wanted, the injection made into muscle or deep connective tissue, as in the lumbar region. I have never seen an abscess or had one occur when given in this way. Usually there is some tenderness. In one case where the apothecary used strong H_2SO_4 and gave 10 gr. in one injection, in the arm, there was a small slough, hardly involving more than the epidermis. I am inclined to believe he had an excess of acid. In another case the resident divided the dose unequally and gave about 8 gr. in one side of the back, the rest, 10 gr., in the other. In the region of the first, on the following day, there was a soft, deep-seated swelling about the size of a silver dollar, with pain all over that side. The side was painted with iodine and pain and swelling subsided, though there was some left on the patient's leaving on the second day. One patient had 30 such injections with almost no pain, and without local evidence.

I have used the bi-muriate with urea, but could see no advantage. Have often intended to experiment with other solutions but so far have not done so. Quinine is given in this way very often in Texas, usually in cases where the danger of an abscess would not weigh with that of risking any other method.

I have given it often merely to see the local effect.

Very truly yours,

GEORGE DOCK.

GALVESTON, TEXAS, June 13, 1891.

Inter-Continental American Medical Congress.

At the regular quarterly meeting of the Golden Belt Medical Society, of Kansas, held in Junction City, Kansas, July 3d, 1891, Dr. W. B. Dewees, President of the Golden Belt, having been appointed a member of the Auxiliary Committee of the Inter Continental American Medical Congress, presented the following resolutions, which were passed unanimously:

Resolved, That this society heartily approve of the permanent organization of the Inter-Continental American Medical Congress, believing it to be of material benefit in promoting the interests and welfare of the medical profession of America.

Resolved, That the members of this society will do all in their power to promote the interests and welfare of the Congress.

Resolved, That the Secretary of this society is hereby instructed to forward a copy of these resolutions to the

Kansas Medical Journal and THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION for publication.

F. B. BROWN, M. D.,

Secretary Golden Belt Medical Society.

-Salina, Kansas, July 9, 1891.

Section on Materia Medica and Pharmacy.

To the Editor:—On behalf of the officers of the Section on Materia Medica and Pharmacy of the American Medical Association, I invite the members to prepare papers to be read at the Detroit meeting of the Association. The first meeting of this section was held at Washington last May, and proved successful in every respect. The titles of papers for the section should be submitted as soon as determined. It will not be necessary to submit the article until a date nearer the coming meeting; for further information address the secretary of the Section, DR. H. M. WHELPLEY, St. Louis.

NECROLOGY.

John Frederick May, M.D.

Dr. John Frederick May was born in the city of Washington, D. C., May 19, 1812, and died of pneumonia, at his residence 2022 G. street, n. w., May 1, 1891. He was the son of Dr. Frederick and his wife, Julia Matilda (Slocum) May, of this city, who were married in 1811.

Dr. Frederick May was a native of Boston, Mass., born in 1773, and a graduate of Harvard College, both in letters and medicine, writing his thesis on *Tetanus* in Latin, a copy of which may be found in the "Toner Collection," Library of Congress. He received his medical degree in 1795. He studied medicine with Dr. John Warren, brother to the patriot, Dr. Joseph Warren, who was killed in the battle of Bunker Hill.

The father of the subject of this sketch settled the same year of his graduation in the, then, infant capital of the United States, five years before the archives of the Government and the executive offices were removed hither. He brought with him letters of introduction to the leading men here at that time; Daniel Greenleaf, for whom Greenleaf's Point is named; Hon. Wm. Cranch, the first presiding judge in the District of Columbia; Notly Young and others. He was a man of genteel and scholarly tastes and possessed excellent business habits, fully identifying himself, from the first, with the interests of the city. He acquired real estate and encouraged business enterprises; was one of the incorporators, and a director for building the first bridge over the Potomac river where the Long Bridge now crosses. He was, also, a promotor of the extension of the Chesapeake and Ohio canal through the city. He was an early and earnest advocate for schools, and filled the chair of Obstetrics in Columbia College from the organization of the medical department in 1825 until his resignation in 1839. For years he enjoyed the leading, and a large practice in obstetrics, and was well qualified to discharge its responsible duties. As a physician he was justly popular, and as a lecturer, entertaining, and at times, pathetically elo-

quent. His wife, Julia M., died October 14, 1823, leaving a family of eight children—six sons and two daughters. The doctor did not marry again, but devoted himself to the education of his children, and had the satisfaction of seeing them all well fixed in life before his death, which did not occur until July 23, 1847. His father—the grandfather of John Frederick—was Col. John May, a leading Boston merchant in his day, and one of the patriots of the Revolution, who, in 1773, disguising themselves as Indians, threw a cargo of tea overboard into Boston Harbor. Col. May's immediate ancestor was Capt. May, a man noted for his courage and prowess in defence of New England against the Indians. The May family came originally from England and settled in Massachusetts in 1632.

Dr. John Frederick, to whom was given the first name of both father and grandfather, came thus of brave and courageous stock, who were among the leading citizens of the community in which they lived. He received a collegiate education at Columbia College, and took his medical degree from the same institution in 1834. Shortly after this, he went to Europe, where he spent more than a year in professional study in the leading hospitals of London and Paris. In this way he familiarized himself with all the latest advances in medicine and surgery. After an extended tour through Europe, the West Indies and the United States, he began to practice in his native city. He joined the Medical Association of the District of Columbia in 1838, his father being president of that body at the time. In 1840, he became a member of the Medical Society of the District. This organization his father assisted in founding, his name appearing in the original charter of 1819, and also in the amended charter of 1838.

In 1839, Dr. John Frederick May was elected to the "Chair of Anatomy and Physiology" in the Columbian College. In 1841, he was transferred, by consent of the faculty, to the "Chair of the Principles and Practice of Surgery." This position he filled most acceptably until his resignation in 1858. He was honored, about the same time, with the professorship of surgery in the University of Maryland, which he filled for two years without vacating his college duties in Washington, and to the satisfaction of his associates in both faculties. Dr. May became also a member of the Section of Physiology and Medicine of the "National Institute" in Washington, a scientific organization antedating the existence of the Smithsonian Institution of this city. This association of physicians was active in 1843, and for a number of years sent delegates to the American Medical Association. Eventually, however, it was merged into, or its functions were absorbed by the Smithsonian Institution. The "Pathological Society of the District of Columbia" was formed about 1846, Dr. May taking an active and influential part in its discussions. In 1848, Dr. John Frederick May was united in marriage with Sarah Maria Mills, by whom he had seven children—six of whom are living, two sons and four daughters. The family of the May's have been noted, for generations, for their fine physical development, bright intellects and honorable traits of character.

In 1847, Dr. May became a member of the American Medical Association, being a delegate from the Medical Department of the Columbian College. In 1858 he was elected to the Chair of Surgery in the Shelby Medical College at Nashville, Tenn., which he filled very acceptably until the breaking out of the "Civil War."

Although Dr. May is best known by his splendid record as a surgeon, he was, throughout his professional career, a general practitioner, and was equally astute, strong and able in each and all the departments of medicine. He took, it is true, great pains to qualify himself as a surgeon, making special studies in anatomy, and equipping himself with the best instruments devised for the different operations obtainable either at home or abroad. Being a man of fine physique, over six feet in stature, and well proportioned, calm and self-possessed, with clear convictions and steady nerve, he was every way suited for the duties and responsibilities of the surgeon. His skill in surgery speedily attracted attention, and placed him in the very front rank of this field of practice in the United States. He was one of the first surgeons of America to amputate, with success, at the hip joint, and the first in Washington to perform ovariotomy. His skill in surgery was widely recognized, so that for years most of this kind of practice in the city of Washington fell to his care. He was surgeon to the Washington Infirmary, which was conducted under the auspices of the faculty of the National Medical College, in which he was the professor of surgery.

Dr. May was punctilious in his intercourse with his professional brethren and with the public, but he was at the same time the soul of honor. He was always ready, on a proper basis, to render service to the afflicted and to advise and assist the young practitioner in difficult cases. He loved his profession, and esteemed the man who, by his merits, won the approbation of the medical fraternity.

Dr. May, while he was a good surgeon and physician, was also an excellent business man, attentive to business matters, making good investment, and accumulating a large and productive estate. He was earnest and zealous in whatever engaged his attention, whether it was his profession or his business investments. In all his affairs he brought a clear, strong judgment to bear, and wasted nothing on sentiment.

Shortly after the war Dr. May removed to the city of New York. He continued, however, to spend much of his time in Washington, attending to his real estate and other business interests. His family, however, returned to reside in this city about 1880. In 1884 he was elected surgeon on the consulting staff of "Garfield Memorial Hospital." He served here faithfully and as president of the medical staff for five years, when the necessity for lessening his duties, owing to the accumulation of his years, induced him to resign.

Of late the Doctor has been a great sufferer from asthma, and particularly at certain seasons of the year. He tried various climates and many places, at the sea level and at high altitudes, but found no place affording more than a modified exemption.

One of his sons, William May, is treading in the foot-

steps of his father, having studied medicine, and being now in full practice, with a predilection for surgery.

Dr. May's funeral took place from St. Paul's Church, Twenty-third street, and was largely attended by the profession, private citizens and former friends of the Doctor's. The Rev. Dr. Harding conducted the Episcopal services. The remains of Dr. May, followed by a large cortege, were placed in Rock Creek Cemetery.

J. M. T.

BOOK REVIEWS.

PRACTICAL PATHOLOGY AND MORBID HISTOLOGY. By HENEAGE GIBBES, M.D., Professor of Pathology in the University of Michigan, etc. Pp. 320, cloth, 8vo. Philadelphia: Lea Bros. & Co. 1891.

In the olden times, instead of writing a preface, the author wrote an "apology" for having written a book at all. One should now-a-days be very sure that there is need, when he undertakes to write a new book. Our author finds the need of a new book on the subject of which he treats, in the fact that photographic illustrations of actual appearances are needed to fill an existing gap in the domain of morbid histology; and the fact must be admitted that our monographs and text-books are filled with illustrations which are rather diagrammatic, than representative of an actual specimen. There is sufficient reason why this should be the case, and that is a pecuniary one. It has been pretty well demonstrated that, in the existing condition of the art of lithography and engraving, we cannot reproduce on ordinary paper, either faithful photographs or well worked out engravings; a higher class of paper must be used; this necessarily increases the cost of the book. The recognition of this fact has heretofore led publishers, both in Europe and America, to publish fine illustrations, when the character of the book required it, on separate sheets from those on which the text of the book was printed, and it may be safely said without successful contradiction, that the book under review affords abundant proof of the wisdom of the common practice. The publishers have endeavored to surmount the difficulty by printing the entire book on extra heavy paper, but a comparison of the illustrations will show that there is still lacking that quality which would bring out distinct tracings. Take, for instance, the illustration of spindle celled sarcoma on page 165, and it is impossible to resist the conclusion, either that the section was cut too thick, or that it was slightly out of focus when the photograph was taken. Photomicrographic negatives are notoriously difficult to reprint from, even with the most careful attention to details, owing to difficulties of illumination, and the fact that, as a rule, they are

made by amateur photographers and not by experts. A comparison of the illustrations in this work with those in Peyer's Atlas of Clinical Microscopy, will show very plainly the difference between photomicrographs reproduced in the book pages and those on separately printed boards. The book itself affords an excellent example of the difference in class and clearness, if one compares the beautiful plate in the frontispiece with the out-of-focus picture on page 177.

The text of the book, so far as it relates to morbid histology, is excellent, and fairly embodies the latest teachings; that with reference to the preparation of specimens, the use of the microscope and the laboratory technique is to be commended. The chapter on practical bacteriology is one of the best in the book, which as a whole compares favorably with others on the subject of which it treats.

COLLECTED CONTRIBUTIONS ON DIGESTION AND DIET, BY SIR WILLIAM ROBERTS, M.D., F.R.S. Philadelphia: Lea Bros. & Co. 1891.

This volume consists mainly of a reprint of the author's Lumbian Lectures on the "Digestive Ferments and Artificially Digested Food," and five lectures on "Dietetics and Dyspepsia" given at the Owens College in 1885. It also contains the other publications of the author on kindred subjects. The subject matter is divided into four sections:

1. Digestion, and the Digestive Ferments.
2. Dietetics.
3. Preparation of Food for Invalids.
4. Dyspepsia.

The section on Dietetics is replete with suggestions on practical points. It discusses many points which have been observed by the clinician, but have not yet reached the more exact physiologist. These ultra-physiological facts of digestion, are of the highest importance to the practitioner, if he be familiar with the facts of digestion as already determined by the physiologist and chemist. The book is in many respects one of the most satisfactory productions on the subjects of which it treats, that has appeared in recent years.

MEDICAL REGISTER OF NEW YORK, NEW JERSEY AND CONNECTICUT, 1891-1892. Published under the supervision of the New York Medico-Historical Society, Wm. T. White, M.D., editor. Vol. 29, press of G. P. Putnam's Sons. This is certainly the most complete physicians' register that has come into our hands. It contains the names of 7,854 physicians, of which there are in New York State, exclusive of New York city and Brooklyn, 3,651; New Jersey, 961; Connecticut, 611; New York city, 2,325; Brooklyn, 778. The increase over last year is 205. Not only does the register of physicians

seem to be complete, but there is also a large amount of useful information, tersely stated, not one line of which would we desire to have omitted.

AN ELEMENTARY HANDBOOK ON POTABLE WATER. By Floyd Davis, M.Sc., Ph.D. Boston: Silver, Burdett & Co. 1891.

A good little book, containing chapters on Pure Water, Inorganic Constituents, Vegetable Constituents, Animal Constituents, Microorganisms, Water Supplies, Natural Purification, Artificial Purification, Systems for Central Filtration, and with an Appendix, having, under Sec. A, The Origin and Home of Cholera, and under Sec. B, Qualitative Tests for Impurities in Drinking Water.

MEDICAL PUBLICATIONS.—HARVARD MEDICAL SCHOOL. 1890.

The preface says: "The following articles are presented in bound form to show the character of the original work done by the instructors of the school, or under their personal supervision." The volume contains eighteen papers, the majority of which have had their origin in the physiological laboratory. The articles, nearly all of which have been published elsewhere, are of the highest scientific standard and are worthy of the great University which fathers them.

MISCELLANY.

DR. W. S. CHRISTOPHER has resigned the chair of Theory and Practice of Medicine in the University of Michigan to take the chair of Diseases of Children in the Chicago Polyclinic.

WANTED.—A few copies of No. 1, Vol. xv, of THE JOURNAL; will pay good price. Send to this office.

DR. H. M. WHELPLEY, professor of Microscopy in the St. Louis College of Pharmacy, and for the past five years a lecturer in the Missouri Medical College, has been elected Professor of Physiology and Histology, and Director of the Histological Laboratory of the latter institution. The doctor has also accepted the position as Secretary of the faculty.

VERMONT STATE MEDICAL SOCIETY.—The following papers will be read at the next annual meeting of the Vermont State Medical Society, to be held at Burlington, October 15 and 16:

1. Summer Diarrhoea in Children, H. D. Holton, Brattleboro. Discussion opened by C. F. Camp, Barre, G. F. B. Willard, Vergennes.
2. Predisposition to and Prophylaxis of Phthisis, A. B. Bisbee, Montpelier. Discussion opened by S. T. Brooks, St. Johnsbury, E. A. Bates, Highgate.
3. The Treatment of Phthisis, A. C. Bailey, West Randolph. Discussion opened by A. P. Grinnell, Burlington, O. W. Sherwin, Woodstock.

4. Recent Advances in Surgery, L. M. Bingham, Burlington. Discussion opened by Henry Janes, Waterbury, F. D. Robertson, St. Albans.

5. The nature, varieties, causes, symptoms and treatment of Glaucoma, J. H. Woodward, Burlington. Discussion opened by C. E. Chandler, Montpelier, F. T. Kidder, Woodstock.

6. Some European Lessons, J. H. Jackson, Barre.

7. Puerperal Septicæmia, H. R. Wilder, Swanton. Discussion opened by C. F. Branch, Newport, H. S. Brown, St. Johnsbury.

8. Heart Sounds and Cardiac Murmurs, D. C. Hawley, Burlington. Discussion opened by J. H. Jackson, Barre, D. F. Rugg, Hartland.

9. A Study of New Remedies, W. H. Vincent, Orwell. Discussion opened by E. J. Hall, Morrisville, F. R. Stoddard, Shelburne.

10. Albuminuria, its Detection and Significance, F. L. Ladue, Alburgh Springs. Discussion opened by Geo. B. Nichols, Barre, W. D. Huntington, Rochester.

11. Pure drinking water and how to secure it, J. H. Hamilton, Richford. Discussion opened by J. D. Haurahan, Rutland, C. G. R. Jennings, Bennington.

12. Indigestion and its Relation to Disease, C. W. Peck, Brandon. Discussion opened by Edw. R. Campbell, Bellows Fall, C. W. Jacobs, Richinond.

13. Preventive Medicine, C. S. Caverly, Rutland. Discussion opened by S. S. Clark, St. Albans, E. W. Shipman, Vergennes.

14. The Upper Air Passages and their Diseases, O. B. Douglass, New York. Discussion opened by J. H. Woodward, Burlington, S. W. Goss, Chelsea.

15. Acute Capillary Bronchitis in Children, W. G. E. Flanders, Fairfield. Discussion opened by Joel Allen Johnson, E. P. Stimson, West Randolph.

16. Patent Nostrums, L. W. Flanders, Burlington. Discussion opened by H. T. J. Howe, Waitsfield, C. J. Russell, Hinesburgh.

17. Shall we Abolish the Lecture System in our Medical Schools? O. W. Sherwin, Woodstock. Discussion opened by A. T. Woodward, Brandon, Geo. Dunsmore, St. Albans.

18. President's Annual Address, J. N. Jenne, St. Albans.

This announcement is issued in order that every member of the Society may have ample opportunity to come prepared to discuss the various papers.

It is especially urged that each member appointed to discuss a paper make special preparation to do so, and that any member who will be unable to fulfil such appointment, notify the Secretary before October 1.

It is expected that other papers will be offered for the programme, and all members are reminded that volunteer papers are always in order.

The annual Banquet will take place on Thursday evening, October 15, after the President's Address, with Prof. J. H. Jackson, of Barre, as Anniversary Chairman.

There will be the usual exhibit of drugs, medicines, surgical instruments and appliances, etc.

It is expected that the usual courtesy of half-fare will be extended by the railroads.

The regular programme will be issued October 1.

D. C. HAWLEY, M.D., Sec'y.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from July 4, 1891, to July 10, 1891.

Asst. Surgeon James W. Buell is retired from active service, by reason of disability incident to the service.

Asst. Surgeon William S. Owen, Jr., detailed to attend the encampment of the Illinois National Guard, near Springfield, Ill., from July 18 to 25, and August 11 to 18, 1891.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending July 11, 1891.

Asst. Surgeon Robert Boyd, ordered to the U. S. receiving ship "Dale," Washington, D. C.

The Journal of the American Medical Association

ORIGINAL ARTICLES.

ON APPENDICITIS AND PERICÆCAL INFLAMMATION. WITH NOTES OF CASES ILLUSTRATING UN- USUAL DIFFICULTIES IN DIAGNOSIS.

Read before the Section of Surgery and Anatomy, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY THOS. G. MORTON, M.D.,
OF PHILADELPHIA, PA.

No subject within the domain of abdominal surgery within recent years, has made such decided progress, or is at the present time, attracting more attention than that of operation for intestinal lesions, whether due to traumatism or disease.

The fact that perforation so frequently complicates perityphlitis, brings the question of the management of such cases prominently before us as surgeons, and requires that we should not only entertain decided convictions as regards the pathology of the affection, but also have well matured opinions as to the details of operating, and upon the time when such operation should be performed with the least risk to the patient, and with the prospect of the most successful result.

PART I.—ANATOMY, PATHOLOGY, AND DIAGNOSIS.

Appendicitis, simple or perforating, with resulting perityphlitic inflammation, or pericæcal abscess, is a comparatively common pathological accident; and its diagnosis and treatment belong both to medicine proper and to surgery. Almost invariably the case is first seen by a physician, and, as the records will prove, very much depends upon his ability to promptly diagnose the morbid condition, and to appreciate the importance, in certain cases, of early surgical operation for its relief, and on the other hand, the gravity of the responsibility assumed in delaying operative procedure until the patient is in a dying condition, or fast approaching it. Upon the physician also usually devolves the duty of acquainting the family of the patient, or the patient himself, of the peril he is in, and of con-

vincing them that delay is indeed dangerous when an abscess has formed adjacent to the appendix vermiformis, and peritonitis is threatening or is actually in progress. The surgeon is interested especially in the diagnosis and details of operation, and in any special dangers or difficulties attending it.

I have thought therefore that this would be an appropriate topic to bring before this section for discussion. Moreover, this subject is attracting a great deal of attention at the present time; so much so, indeed, that the American Surgical Association, and other societies have repeatedly had it up for consideration within the last few years, and it has more than once received contributions from our own proceedings. At its meeting in December, 1887, three papers were read before the County Medical Society of Philadelphia: One on the "Pathology of Pericæcal Inflammation," by Dr. John H. Musser; one upon "Diagnosis," by Dr. William Pepper; and one upon "Treatment," by myself, by invitation of the society. In my communication, the indications for the operation, its technique, and details of after-treatment, were clearly indicated. I may say now, more than three years later, that subsequent events have not lead me to abandon, but rather to confirm, the views then expressed as to diagnosis and treatment. I then presented a case which had been operated upon by me in the spring of 1887, in the manner prescribed in that paper, which made an excellent recovery after removal of an ulcerated and perforated appendix. I have reported a number of others since that time, showing the importance of early diagnosis, prompt operation, exploration of the abscess cavity and removal of the cause of the mischief. The case just referred to, I may say, was the first recovery on record, so far as I am aware, where the radical operation of amputation of the appendix was deliberately undertaken for the relief of pericæcal abscess. This alone is sufficient to show how recently the subject has claimed the attention of the profession.

This operation just referred to, has already become one of the established procedures of surgery. It is somewhat surprising, therefore, to learn that some surgeons still use the aspirating needle in the diagnosis of abscess, and do

not consider it of vital importance even to remove the appendix in the treatment. And yet this is what a western surgeon reports that he witnessed when on a recent visit to the Metropolis (*American Practitioner and News*, Louisville, Ky., Vol. x, page 380).

This, to say the least, betrays a deplorable want of agreement among surgeons and teachers of surgery as regards one of the most vital questions of operative treatment, and even the means of diagnosis.

I think that the present state of abdominal surgery will support me in stating that, as a rule, in any abscess of the ileo cæcal region, appendix disease should be suspected, and in such case the organ should always be sought for, in order to ascertain its condition; unless this is done the very first principles of correct treatment are violated. If a diseased appendix be permitted to remain it is liable to set up further mischief. In such a case, as the rule, the future welfare of the patient demands that it should be excised, unquestionably so if inflamed, perforated, or containing foreign bodies.

It seems surely as if enough had been said, with regard to the dangers of using the exploring needle, of its utter unreliability, and of its inability to afford information of any value in these cases, to cause its complete abandonment, especially by surgeons who occupy important and responsible positions as teachers and operators, and who aim to serve as guides for others.

A brief review of the pathology of appendicitis, I think, will make it clear to us all, that the life of the patient often depends upon the ability of the medical attendant to promptly recognize the cause of the disease, and to early institute the proper measures for its relief and very often its removal, as the only way to afford relief and permanent safety to the sufferer.

In taking up the systematic discussion of this subject it is perhaps better to very briefly recall the anatomical relations of this part of the body, and the position of the appendix in health and disease.

Anatomy.—From a number of dissections of bodies where death has been produced by disease not affecting this locality, made by me and under my direction at the Pennsylvania Hospital, and elsewhere, I can supplement the very meagre and often incorrect notices of the anatomy of the appendix usually contained in our text-books. In the first place the opening into the appendix from the cæcum is not patulous, as it is represented ordinarily; this opening is also occluded by any abrupt change of direction of the process by which it often becomes parallel with the bowel. This places a valvular fold of mucous membrane directly over the opening which usually closes it as effectually as the foramen ovale is closed in the heart during the first few days

after birth. Moreover, it is stated by good authority that the calibre of the appendix internally is about the size of a goose quill. I question very much the accuracy of this statement in any case, as I have never found it to be anything approaching this size in health; and rarely, if ever, is it distended throughout its course, by secretion to such an extent as this; ordinarily there is no cavity at all, as the walls are collapsed, and I have found that a good sized probe was as much as could freely pass through the canal.

The opening into the appendix is visible upon the inner (left) side of the lower and posterior extremity of the cæcum; it is covered with the folds of mucous membrane and occluded by mucus under ordinary conditions. Were this not the case, and the opening patulous, as is so frequently figured (especially if the calibre were as large as some have represented), appendicitis would be a far more common affection than it is; and, indeed, few children would live to attain the age of adult existence. In length, the appendix varies from two to five, or even nine inches, as I found it in one case. It varies in normal position and direction; so that it can scarcely be said to have normal position; most frequently it is found upon the posterior and inner (or left) side of the cæcum and ascending colon, extending upward towards the liver or gall bladder, to which it may be adherent. The free extremity often points toward the spleen, but it may fall down into the pelvis, and become adherent to the broad ligament or right ovary, or it may become twisted around the small intestines, forming a loop which may cause obstruction or strangulation of the bowel, or finally it may become part of an inguinal or scrotal hernia. At its base the appendix joins the cæcum, obliquely, on the posterior and inner side, just below and on the same side as the ileo cæcal valve, but not at the lowest portion of the cæcum. The summit of the appendix or free extremity is rounded and imperforate. Upon splitting it open, longitudinally, you notice the comparatively great thickness of the walls, both the mucous coat and submucosa being well represented. The glands in the mucous membrane secrete a small amount of mucus, which, with the epithelial debris, is gradually discharged into the cæcum. Should the opening into the cæcum become impervious from any cause, these secretions may gradually accumulate and become inspissated, forming casts or round balls, resembling cherry stones, but consisting of sandy and organic matter. Such secretions are very common.¹ The follicles of Lieberkuhn are numerous

¹ In 13 consecutive post-mortems made by me in persons who died from other causes than intestinal disease, the appendix in every instance but one contained fecal concretions. In a number, the foreign bodies were quite soft, others were firm, some gritty, yellow or brown in color. The canal of the appendix in several was blocked for an inch or more by a series of such fecal masses, which resembled mice dung. Such material imprisoned may readily excite irritation, inflammation, ulceration and finally perforation and abscess.

in the appendix, and the agminated Peyerian glands are also well developed near the summit of the tube, according to the late Prof. Henry H. Smith, who was also inclined to think that a gland or two of Brunner might also be present. In the lower animals, especially among the rodentia, the appendix is much larger than in man and is so richly endowed with glands as to fulfil an important purpose in digestion. The canal of the appendix is also relatively, much larger in the infant than in the adult.² In the newly born infant the appendix frequently contains meconium.

Dr. Formad, Coroner's Physician and Pathologist in the Philadelphia Hospital, confirms the above observation with regard to the presence of glands in the appendix, and states that he had frequently met with typhoid and tubercular ulcerations and catarrhal changes in the vermiform appendix as a part of a general disease of the mucous membranes of either the large or small intestines. He also has found "Fæcal matter and concretions exceedingly common in the vermiform appendix, surely much more common than is generally held."³ Authentic cases have been recorded by Morgani, John Hunter, Meckel, Haller and others, where the appendix was wanting in otherwise normal individuals. I think that as regards its functions nothing need be said. Whatever relation it may have to the act of digestion in some of the lower animals, in man it is merely a rudimentary organ, having no function, since it may be naturally absent without affecting the health of the individual, and after its removal by operation, the patient has perfect digestion and suffers no inconvenience from its loss. Speaking from a surgical standpoint, it would seem that the principle function of the appendix is to get inflamed and cause peri-typhlitic abscess.

PATHOLOGY.

The chief interest in the pathology of appendicitis lies in the relation existing between disease of the appendix and pericæcal inflammation and abscess; a relation which, in many cases, is very intimate and easily demonstrated. Pathologically as well as anatomically, the appendix is part of the cæcum; its structures are continuous, and inflammation or other morbid process may extend from one to the other, and yet as a matter of experience, it is generally found that the appendix may be the seat of inflammation, even perforation or gangrene, while the cæcum remains unaffected, or at the most is only affected

secondarily. As to the cause of appendicitis, it appears to be always traumatic, or at least the inflammation and ulceration is due to the presence of retained secretions, or of a concretion which acts as a foreign body, oftentimes the inflammation being excited by a blow or unusual physical effort. I repeat that irritation, inflammation, and perforation of the appendix is most frequently, if not invariably, caused by the presence of foreign bodies in the canal of the organ. Such substances are usually phosphatic, or fæcal concretions or small objects aggregated which have gained entrance, or the ordinary secretions of the canal may be condensed into concretions made up of epithelial or other constituents. The retention of such material may be caused by stenosis of the cæcal opening, or by thickening of the mucous coat, or by any abrupt change in the position of the appendix which occurs when the organ becomes adherent to the cæcum, so that the outlet of the organ becomes more or less blocked. While it is popularly believed that such concretions are originally foreign bodies, such as grape seeds or cherry pips, this is rarely the case. In the great majority of cases the masses are more or less globular, others are shaped like small date stones, moulded to the interior of the canal, evidently a collection from mucous secretion which deposited phosphate and carbonate of lime upon a nucleus of fæcal origin. As previously intimated, some of the cases are due to occlusion of the canal, and are attributable to retained secretion. Many undoubted cases have been reported, however, in which foreign bodies, such as pins, needles, oyster shell, small seeds, etc., have entered the appendix from the bowel, and caused perforative appendicitis.

In default of a more satisfactory classification of cases of inflammation of the appendix and its results, I feel justified, after considerable experience, in recognizing three varieties or groups of the affection.

First group—*Irritation or inflammation*. Cases of simple irritation or inflammation of the appendix during the first attack, cannot be positively recognized, but the recurrence of such an attack, establishes a strong probability of this diagnosis.

Every practitioner is familiar with ordinary appendicitis; the symptoms are quite characteristic; the disease is not infrequent and is generally soon recovered from. Recurring attacks also are very common, the intervals being variable, from a few weeks to several months, or, as in some cases, years may intervene. If the cause has been due to some irritating foreign body, and the organ has been able to discharge its contents into the cæcum, a permanent recovery may result, but such favorable termination rarely occurs. If the disease arose from retained secretions, which have been gotten rid of, atrophy of the appendix

² Prof. Leidy, under date of February 27, 1881, in a note to me says: "I have observed the appendix varying from about three to nearly six inches in length, but have never seen such a case in which it was absent. In the infant it appears to be less abruptly an extension of the cæcum, that is to say, from the subsequent greater proportionate enlargement of the latter, the appendix becomes a more abrupt extension."

³ Dr. Toft of Copenhagen, who, while prosecutor to the Royal Frederiks Hospital, found residua of appendicitis in the form of adhesions in 35 per cent. of all post-mortem examinations made.

may follow on the subsidence of the inflammation and the organ become a cord-like body, no longer liable to internal disturbance. If the appendicitis be due to minute solid bodies, attack after attack is likely to occur, and as these increase in size, the probability of ulceration of the mucous membrane from pressure is likely to increase as time goes on.

Second Group:—Inflammation, ulceration, or perforation. Any case of mild appendicitis belonging to the first group of cases may pass to the second. As a result of attacks of appendicitis of a more or less severe type, lymph exudation is thrown out, not only about the appendix, but upon and around the neighboring structures. If upon the intestines, such exudation may occasion bowel paralysis, or bands of lymph may involve the intestine subsequently in absolute destruction. So, likewise, lymph may be exuded in sufficient amount in all directions on the peritoneal surfaces, and form a barrier more or less complete, sufficient to protect the general peritoneal cavity from septic contamination, when abscess forms in the pericæcal region. In other cases the exudation forms a distinct abscess wall completely encysting the appendix, and constitutes the distinct tumor, so often observed in such cases; it is usually well defined, immovable, more or less dense, and painful to pressure. Although it may contain pus, as a result of perforation of the appendix, there is no fluctuation until the tumor increases in size; as it approaches the surface, the superimposed tissues become œdematous. Such abscesses may open through the abdominal wall, and so establish a fistula between the bowel, the abscess cavity and the external abdominal surface, or at any other point where the abscess should tend.

This lymph exudation which surrounds the appendix when ulceration and perforation is imminent, may appear very quickly; the results of perforation are thus emptied into the lymph mass, and are held absolutely encysted. As the pus increases in the interior of the tumor, the exudation of lymph may increase, or the wall of the abscess may become thinner, and so the abscess may burst into the peritoneal cavity, or into the superimposed cellular tissue. The formation of pus due to a perforated appendix is announced by most characteristic symptoms if the pus come in contact with the peritoneum; but when the appendix perforates into a lymph tumor, the peritoneum is guarded, and the symptoms of pus formation are not so marked; indeed there are frequently no symptoms whatever which would indicate such an accident.

Third Group:—Ulceration and Perforation, with insufficient lymph protective walls.

Many of the reported cases belong to this class. The symptoms appear suddenly, and present

the gravest characters. Now, and then especially in children, the disease advances with intense rapidity, the patient early entering a condition bordering on collapse; such cases I have seen terminate fatally in forty-eight hours, or even less time. Careful inquiry revealed in every case, the fact of a former attack of appendicitis. In such cases when perforation happens, there is either no lymph protection to the peritoneum when the accident occurs, or else the exudation has been insufficient, so that when sloughing or perforation takes place, the contents of the appendix and the sloughing tissue are at once brought into contact with the general peritoneum. Such cases are early associated with symptoms of unusual depression, and often profound collapse.

DIAGNOSIS.

*First Group of Cases:—*Pain is usually the earliest and most common symptom of appendicitis. It may come on suddenly or the reverse, be slight, resembling colic, or severe in character; it is usually increased by pressure. There may be nausea and vomiting, and a coated tongue and constipation are commonly present. There is generally some acceleration of pulse, and a slightly elevated temperature. The ileo cæcal region is generally tympanitic. Sooner or later all these symptoms may disappear and convalescence apparently be established. As I have in former papers pointed out, the occurrence of symptoms such as above detailed, especially if there has been a relapse or recurrence, are serious enough to give rise to grave apprehensions for the future, for in a patient with a diseased appendix, a blow, slight local injury, undue exercise, straining, constipation, or even an attack of indigestion, may provoke a recurrence of irritation in the already diseased organ which may lead to inflammation, ulceration, and perforation. Such cases as I have detailed, which do not proceed to ulceration and perforation, are of very common occurrence; under appropriate treatment they go on to apparent recovery. I believe, however, in all cases of pericæcal irritation or inflammation (or, at least, in by far the great majority of such), the appendix is the source of, and responsible for this condition; the danger is therefore not overcome by the subsidence of the symptoms even if such are ever so mild. The subject of such an attack or attacks, may recover by discharge of the contents of the appendix into the cæcum; or through atrophy of the organ or adhesion to the cæcum with more or less complete obliteration of its calibre. But such a favorable result must be very exceptional, and its occurrence in any given case cannot be depended upon.

*Second Group:—*Incident to the inflammation, consequent upon repeated attacks of appendicitis, adhesions may take place, which involve not on-

ly the adjacent intestine, which may cause more or less obstruction, but as a result of such attacks, lymph exudation takes place, often in large amount, which may completely envelop the appendix.

It is this exudation which forms the tumor in such cases, so that when perforation occurs, the pus does not gain access to the general abdominal cavity, but remains encysted; if this protection did not frequently exist, perforated appendicitis would be a much more fatal affection. This tumor wall is often quite dense and thick; when its contents increase the sac distends proportionately, or if more or less thin, the abscess may open and discharge its contents, either into the peritoneal cavity or into the superimposed tissues and reach the surface, or in some cases, by attachment and perforation, be emptied into intestine, bladder, or other organ. Such abscesses are far less serious than those which are found in the third group, where the appendix has no encasing lymph wall. In the former, or second group, although as already stated, pus has formed, it is completely encysted in a tumor, similar to such formations in the ovary or tube, with no special early symptoms necessarily indicating pus formation.

Third Group.—When in addition to the symptoms of appendicitis, those of a far graver nature appear suddenly, viz.: intense local, afterwards general, abdominal pain, marked tympanites, a fluctuating temperature, reaching 102° or even higher, with slight or decided rigors, moderate or profuse sweatings and prostration, there can be no question of the advent of acute perforation and abscess formation in close contiguity to peritoneal surfaces. In such cases where the patient, who has been apparently in perfect health, is suddenly stricken with such grave symptoms, indicating perforation—and I have seen a number of such—careful questioning always reveals the fact that the patient has had one or more attacks of appendicitis, but often so trivial as to be almost forgotten. The history of the former attacks, however slight, therefore, would clear the way for establishing a positive diagnosis.

Although it may be possible for inflammation and abscess to occur quite independent of the appendix in the pericæcal region, yet such instances must be exceedingly unusual. Several years ago (in 1886), I opened a supposed uncomplicated pericæcal abscess of large size; apparently there was no communication with the appendix or cæcum, the walls of the abscess seemed to involve only the connective tissues. The patient recovered, but subsequently suffered from attacks of pain in the same locality, which were then judged to be from a diseased appendix; suddenly, and nearly two years afterwards, the symptoms of perforative appendicitis and peritonitis appeared; there was no tumor, the ileo cæcal region

being markedly tympanitic; section was promptly made, which discovered an abscess and commencing general peritonitis. The lymph exudation was recent, the original abscess walls had been absorbed, so that there was no protection to the general abdominal cavity. The appendix was found enormously enlarged and perforated; it was excised, and the patient has since married and has continued in perfect health. Had the second abscess not formed, the case would have been judged to be a simple pericæcal abscess. While there is every reason to believe that all acute abscesses in the appendix region are due to some lesion of this organ, there is no special reason for the occurrence of simple typhlitic abscess.

I repeat, that it is very doubtful if those cases of perityphlitic inflammation, which under appropriate treatment, go on to convalescence, are cases of inflammation purely of the walls of the cæcum, and connective tissue; such a condition possibly may occur, but it is more probable that in every case the irritation arises in the appendix, with more or less a local peritoneal inflammation. Then again, in every case in which I have excised the appendix for perforative inflammation, there has been a history of former attacks, the symptoms of which corresponded with those which some clinicians describe as indicating typhlitis. In order to determine the presence of an abscess cavity in the ileo-cæcal region, if the symptoms detailed would not be considered sufficient, rectal examination might be made, but I have never been in the slightest degree aided by this procedure.

DIFFERENTIAL DIAGNOSIS.

It, probably, is impossible to differentiate disease of the cæcum from appendicitis at an early state of the malady, as their relations are so close and they both give rise to similar local disturbance. Both organs are covered by peritoneum through a variable portion of their extent; both are liable to irritation, inflammation and perforation.

Perforation of the appendix is a very common accident, while the reverse is true with regard to the cæcum. Even in those cases where cæcal perforation has occurred, it is most likely the result of previous appendix perforation or disease.

One such case occurred in Pennsylvania, under the care of Drs. Rich and Sailor Brown, of Williamsport. I saw the patient in consultation. On the second day after the removal of the gangrenous appendix, fæces came from the wound, and upon careful inspection, two gangrenous perforations were found involving the cæcum. At the time of the appendix removal, the cæcum and colon were markedly impacted and discolored; the violent inflammation about the appendix had extended to and involved the intestine. The resulting gangrene was due in part to con-

tiguous inflammation and in part to impaction. But if this abscess cavity had been simply opened and the appendix not reached, the subsequent appearance of fæces would apparently have established the diagnosis of simple cæcal perforation, while the lesion of the appendix would have been overlooked.

The history of previous attacks of pain in any given case would establish the diagnosis between perforative cæcitis and perforative appendicitis in favor of the latter; at any rate, the necessity for operation being the same in both, the final diagnosis can be left until section has been made.

From Acute Intestinal Obstruction:—The symptoms in intestinal obstruction advance very rapidly, even more so than in appendicitis. In volvulus there is usually more severe pain, which is referred to the umbilicus. Intussusception is accompanied by frequent desire to stool and discharges of mucus and blood; an examination by rectum will probably establish the diagnosis, which also can be said of impaction. Finally, obstruction may be simulated by the attending peritonitis owing to the paralyzing effect on the bowels.

Strangulation of the bowels, intussusception, peritonitis, volvulus, generally come on very suddenly. Impaction of fæces, psoas or iliac abscesses or tumors, come on gradually. Cæcitis and perforative ulcer of the cæcum are also more or less rapid in their course, and point superficially more quickly than does the abscess to which appendicitis gives rise.

From Spinal or Perinephritic Abscess:—Attention to the history of the case and to the local signs of the disorder will enable us to diagnose these forms of abscess. The treatment being almost identical, at least as far as laparotomy is concerned, we need not waste time in making refinements of diagnosis, although the differential diagnosis can generally be made.

In psoas abscess difficulty may be experienced at times in differentiating it from pericæcal inflammation. But in the former there is generally dorsal pain and gastric irritation, and a history of long continued ill-health. Abscess from Potts' disease generally points to the groin, either just above or below Poupart's ligament. It also is associated with ill-health and difficulty in walking. In abscess of the right ovary and tube, the history and digital examination of the case would usually establish the diagnosis. An abnormal pouch or diverticulum of the ilium occasionally is found in the right iliac region, and might complicate the diagnosis, which could only be cleared up after section.

Tumors, both malignant and non-malignant, may be found in this region, but as a rule little difficulty need be experienced in clearing up any doubt. Their physical characters and clinical history are usually sufficient.

When pericæcal abscess points in an anomalous situation, all available diagnostic skill will be required to affect a diagnosis. Unlooked-for complications also may arise, which the surgeon must expect, and which he must always be prepared for. Some of the difficulties which occasionally confront us in making a diagnosis are well illustrated in the following cases:

APPENDICITIS; LATERAL SECTION; OPERATION COMPLICATED BY AN ENLARGED, ELONGATED GALL BLADDER; APPENDIX AMPUTATED, AND THE STUMP INVERTED INTO THE CÆCAL CAVITY. RECOVERY.

Mrs. E. S., aged 46, came under my care January 5, 1891, with symptoms of appendicitis which had existed for a week. Pain had been a prominent symptom, with elevation of temperature, abdominal distention, constipation, furred tongue, and persistent vomiting. Directly over the ileo-cæcal region there was a tumor which was slightly movable and exceedingly painful upon pressure. There had been no previous attack of pain in this region, no chill and no sweating. The symptoms pointed to irritation or inflammation of the appendix or pericæcal region, but not to abscess; but the presence of the tumor was very puzzling, and its character could not be made out. These were the symptoms indicating a first attack of mild appendicitis, and yet a large circumscribed tumor, painful to pressure, was likewise present; but the fact that this tumor was somewhat movable led to the view that it could not be connected with the appendix; at all events, it seemed proper to open the abdominal cavity, explore it, and examine the appendix, and then to be guided by circumstances.

A lateral section was made on the eighth day. Upon entering the abdominal cavity, the tumor proved to be an immensely elongated and distended gall-bladder, which was about five inches in length, lying directly above the appendix region, and in size and shape resembling a small banana. A careful examination of the liver failed to show the presence of any gall stones. The appendix was found greatly thickened, but free from adhesions. It had an extensive mesentery, which was ligatured and removed with the appendix. The stump of the latter was inverted, and invaginated into the cæcal cavity. The peritoneum was then brought over the inverted tissues by five sutures. The wound was closed with deep and superficial interrupted sutures; drainage was not used.

An excellent recovery followed, and the gall-bladder has apparently resumed its normal size.

Dr. Morris Longstreth, who examined the appendix, reports: "Great hypertrophy and thickening, especially of the mucous coat, and ulceration in two places, which appeared to correspond with the enlarged solitary follicles."

GANGRENE OF THE APPENDIX VERMIFORMIS,
WITH NECROSIS OF MESENTERY AND ILIUM;
PERICÆCAL ABSCESS WITHOUT SPECIAL
SYMPTOMS. LAPAROTOMY. DEATH.

On Tuesday, March 6, 1890, in response to a telegram from Dr. Phillips, of Trenton, N. J., Dr. DaCosta and I visited a patient with him in consultation. The message stated that the case was one of volvulus, and requested me to come prepared to perform laparotomy. The patient, who was about 42 years of age, had been apparently in robust health, had remained indoors on the preceding Saturday. He had been constipated, for which a laxative had been given, but no relief was obtained. All efforts during the succeeding four days to procure an opening of the bowels signally failed. During this period there was no special symptoms except nausea, and occasional vomiting. After a careful and thorough examination, we were unanimous in the opinion that a positive diagnosis could not be made at that time. It was stated that there had been little if any pain in the abdomen, which was not abnormally distended; the temperature had been normal; there had been no chills or rigors; no acceleration of pulse; the principal symptom being simply a refusal of the bowel to respond to cathartics and enemata. There seemed to be more of a bowel paralysis rather than obstruction from twist or invagination. There was no symptom of peritonitis or other grave lesion of any of the abdominal contents. On inquiry, it was stated positively that there had never been any previous attack of pain in the appendix region. After a most careful consideration of the case, we were unanimously of the opinion that the idea of an operation could not at that time be entertained, and was not justifiable, but agreed that calomel should be administered in fractional doses, $\frac{1}{10}$ of a grain every half hour, with an occasional dose of podophyllin, and as much nourishment as possible.

On separating it was understood that we should hear, promptly, if there was any unfavorable change. Early the next morning Dr. Phillips telegraphed: "Treatment agreed upon yesterday has been carried out; general distress and distention increasing; strength is less, temperature sub normal. I think, as does the patient, that the operation should not be deferred." Upon my second visit, I found the patient with marked hiccough, and an irregular feeble pulse with slight abdominal tension, and no marked pain. There had been no movement of the bowels. The belief that some grave lesion existed, was warranted by the prostration, the sub normal temperature, the weak pulse and the loss of strength, but there was no evidence of peritonitis, local or general. In other words, the symptoms were negative, and it was impossible to clear up the diagnosis even at this time. Al-

though the patient was in an exceedingly grave condition, I quite agreed with Dr. Phillips that an exploratory operation was justifiable. Ether was administered, a two inch incision was made in the median line, and an exploration was made with the finger. To the left of the umbilicus, and extending from just above to just below its level, was a mass of collapsed intestines, but nothing abnormal was found, except slight distention, in any portion of the abdomen until the exploring finger was carried deeply into the right iliac fossa, where it plunged into a very foul abscess, and pus flowed freely from the wound. The incision was then considerably enlarged. In this cavity was found an enormous appendix vermiformis, inflamed and gangrenous in places which was ligated and cut off. The boundaries of the pus cavity comprised the under surface of the cæcum and ascending colon, iliac fossa, mesentery and portions of the small intestine. The portion of the wall made up of mesentery, was necrotic for quite a distance at or very near its root, and the ilium was covered with lymph, and for some inches showed structural change. The sloughing portions separated as soon as touched and bled vigorously. The bleeding vessels were taken up by ligatures, in part individually, and in part *en masse*. Evisceration had been necessary to get at and tie off the appendix. The intestines were now, with some difficulty, returned and the abdominal cavity thoroughly washed out. A glass drain was carried deeply into the pelvis, and the parietal wound sutured.

It was expected that extensive necrosis of the intestine would occur, if it had not already started, because of the condition of the mesentery. No other operative resource seemed possible in this most desperate case.

The presence of such serious disease was a matter of profound surprise, and was totally unexpected, for none of the symptoms pointed to the existence of such a complication, and the diseased conditions could not possibly have been diagnosed by the symptoms. It is most extraordinary that such destructive changes could have existed without symptoms indicating such lesions, and I know of no instance, in my experience, where such disease existed without equally positive symptoms. The only symptoms which heralded the grave condition, subsequent to the visit of Dr. DaCosta and myself, were those already alluded to, viz.; the hiccough, irregular pulse, sub-normal temperature and failure of strength.

Subsequent to the operation there was a marked improvement in every respect; this was due to the removal of the purulent matter, and foul contents of the abscess cavity, while the fatal result which took place two days subsequently was due to exhaustion incident to the gangrene.

The question was raised at the time, whether or not, if the operation had been performed on the day Dr. DaCosta and I saw the patient, the result would have been different. To this I replied, that after the most careful consideration it was agreed that the safest course was to wait; that the diagnosis of volvulus and intussusception was abandoned, as well as peritonitis; of the latter, indeed, there was not a symptom present. Indeed, had laparotomy been performed twenty-four hours earlier we would have found almost precisely the same fatal conditions, for such extensive disorganization is of slow and not so rapid growth. Dr. DaCosta, having read this report, has written: "I have read the above and concur entirely; no earlier operation could have had a different result."

In reviewing the history of this case, I am at a loss to be able to see in what way a diagnosis of such a condition could be made; for it seems almost impossible that with inflammation, abscess, obstruction of the bowels, from lymph and gangrene, there should not have been some positive symptoms. On making further inquiries subsequent to the operation, it was stated by a member of the patient's family, that about two years before, the patient had a serious but brief attack of pain in the appendix region, which was not relieved until after the administration of a hypodermic of morphia; so that, unquestionably, the appendix had during this time been diseased, and was the cause of the fatal attack. Had the fact of a previous attack of pain in the ilio-cæcal region been known prior to the operation, it would have been sufficient to elect a lateral instead of a median section, but at the time we were called to the case, it would not have made any difference in the ultimate result.

PROBABLE PERFORATIVE APPENDICITIS; ABDOMINAL TUMOR SUPPOSED TO BE MALIGNANT; EXPLORATIVE LAPAROTOMY; DIAGNOSIS OF MALIGNANT DISEASE RE AFFIRMED; SUBSEQUENT DISCHARGE OF AN ABSCESS INTO THE URINARY BLADDER; CLOSURE OF FISTULA. RECOVERY.

On the 23d of last June, Mr. T. H. W., aged 33, from North Carolina, came under my care, as a private patient, in the Orthopædic Hospital, with the following history.

About six months previously, or just before Christmas, in 1889, he first had pain in the lower abdominal region; more frequently at night, and was very constipated. The pain lasted about ten days, then gradually subsided, and during this time he was obliged to lean forward in walking, owing to a sense of drawing. About the 25th of April following, when in Scranton, Pa., after feeling poorly all day, he experienced a very severe attack of pain in the lower abdominal region, which lasted for many hours, and was only

relieved temporarily by opium and hot applications. Two days later, although very weak, he went South. On the journey he had a very severe chill, which was followed by fever and pain, the latter continuing all the time; his temperature ranging from 100° to 101°; at the end of ten days he was compelled to go to bed, blisters were applied on account of pain. A hardness and swelling now appeared somewhat to the right of the median line, but below the umbilicus. The diagnosis of local peritonitis was then made; mercurial ointment was applied (which subsequently caused salivation), and low diet ordered. His temperature ranged from 96° to 102°. His condition finally became so alarming that he concluded to come North. On the way up, he consulted Dr. Hunter McGuire, at Richmond, Va., who suspected an abscess and suggested the use of the exploring needle. This was declined, and he reached Philadelphia on June 16th. He was admitted to the Pennsylvania Hospital under the care of Dr. Ashurst, who diagnosed carcinoma of the omentum and bowel. After remaining a week in that institution, he placed himself under my care, as a private patient, and entered the Orthopædic Hospital.

At this time I found him emaciated, with great loss of strength, a temperature not much above 100°, but fluctuating. On examination I found marked hardness of the tissues in the anterior belly wall, a considerable tumor which extended from just below the umbilicus to the bladder region, situated over the right iliac region, but not completely. The tumor was hard, more or less irregular, and painful to deep pressure.

The history of the case was that of local peritonitis, and the symptoms pointed to deep abscess, yet as the more marked hardness and tumefaction was confined to the central abdominal region, the question as to the appendix being the source of the trouble was held in abeyance. Hot fomentations were applied, and large amount of milk, nutritious foods and stimulants were ordered.

A few days later I left the city for a trip to the Pacific Coast. During my absence the patient had another acute attack of pain, with marked fever; the only comfortable position he could secure was with the knees drawn up and his body bent forward. Dr. Agnew was called in, who confirmed the diagnosis of malignant disease. After a residence of three weeks in the hospital the patient went to Scranton, and was under Dr. Logan's charge. He subsequently got very weak, his temperature ran high, his pain was severe, and there was progressive loss of flesh. On August, 3 Dr. Mordecai Price visited the patient at his home, and an exploratory abdominal incision was made; the intestines and omentum, it is stated, were found matted together by what was pronounced to be carcinoma, and the opinion

was given that he would probably not live through the month. For a week the patient was in a bad condition, chiefly due to obstinate constipation, high temperature, severe pain. Three days after the operation he passed per urethram, what seemed like the "stem of a water lily," of a reddish black color (probably a blood clot). He had great burning at the end of micturition, and the urine had a foul odor and contained pus. At times, subsequently, the amount of pus was one-third of the urine passed; gradually the pus disappeared and the urine apparently became normal, of natural odor and color, and would so continue for periods varying from five days to two weeks, the latter being the longest interval. It was very noticeable that when the pus was not discharged from the bladder the patient's temperature increased and general symptoms were less favorable. He frequently passed in the urine, masses of brownish or slate colored tissues in a state of decomposition. This continued right along until early in December, although he gained some 15 pounds in weight, when I visited him at his home in Glenburg, near Scranton. He was then in bed and passing large amounts of pus with the urine; and then, for the first time, considerable gas escaped by the urethra, especially at the close of urination. On further examination, I found that subsequent to the exploratory laparotomy and the discharge of pus, that the tumor or hardness of the abdominal wall gradually lessened, and finally disappeared, with the exception of a slight hardness which led from the bladder region to the right iliac region. A careful survey convinced me that the patient was the subject of a fistula which had extended from the appendix, that this organ had been originally inflamed, had become surrounded by lymph, had subsequently perforated when abscess formed, that the adhesions had taken place with the abdominal wall, and finally the pus track led on to the bladder, into which an opening took place, through which the abscess contents, pus, foreign matters, and gas were discharged. The patient was placed on milk, with directions to increase the amount to three quarts daily, also extract of malt and as much nutritious food as could be digested. When his condition warranted, I advised that he should come to Philadelphia for a section and removal of the appendix. His condition after this improved rapidly, no further abscess appearing. He came again to the Orthopædic Hospital on December 27. From that time, however, he improved rapidly, gaining nearly a pound a day, and was soon able to walk out. The hospital record states: "The abdomen is neither scaphoid or prominent; below the cicatrix of operation and towards the pubes there is some slight but deep induration, but no tenderness." Urine was examined and found to be normal. It seemed reasonable that with the im-

provement of health the fistulous track might have closed naturally, so that on January 12, after a short residence in the hospital he was discharged apparently cured, with the understanding that should any further evidence of the trouble appear, the source of it should be investigated and eliminated by abdominal section. He is at this time apparently quite well.

The following case illustrates the grave danger which arises from bands of lymph adhesion, which are liable to be thrown around the appendix as a result of repeated attacks of appendicitis. Such adhesions may prevent the surgeon, at the time of the operation, finding the perforated organ, which not being removed, is likely to give rise to fæcal fistula; and I have seen several such cases

PERICÆCAL ABSCESS; LAPAROTOMY; ADHESIONS; APPENDIX NOT DISCOVERED; RECOVERY WITH FÆCAL FISTULA; FIVE MONTHS LATER ABDOMEN RE-OPENED, FISTULA FOUND AND CLOSED; RECOVERY.

George I., aged 30, a patient of Dr. Benj. F. Butcher, of Philadelphia, was admitted into the Pennsylvania Hospital, May 12, 1890, in an exceedingly prostrated condition, with a history of former attacks of pericæcal inflammation, the last being followed by symptoms indicating perforation of the appendix and abscess.

The attack came on suddenly, with pain in the appendix region, which was greatly increased by pressure; there was nausea, fever and constipation; later on there was a sudden accession of intense pain with deep swelling, and general abdomen tenderness and tympany; a fluctuating temperature, chills and profuse sweatings. The skin over the ileo-cæcal region became discolored, somewhat cedematous, but no distinct tumor could at any time be felt, yet there was some hardness of the deep tissues.

Such was the condition in May, 1890. A lateral incision was made directly over the region of the appendix, which exposed a large abscess cavity containing foetid pus; careful search failed to discover the appendix, but the surroundings were so matted together by adhesions that further exploration was not deemed prudent. It was supposed that the entire appendix had sloughed from the violence of the inflammation, which had doubtless resulted in gangrene of the entire organ.

The abscess and abdominal cavity were thoroughly washed, and two drain tubes were inserted, one of glass to the bottom of the abdominal cavity, the other a rubber tube into the most dependent part of the abscess cavity. A rapid recovery followed, but a fistulous opening remained which now and then discharged excrementitious matter, showing that an opening existed into the intestine, which was probably at site of appendix.

In October, I made a second section, for the purpose of closing the fistula. The incision was made directly in line with that of the first operation; on reaching the cæcum it was found that all the adhesions which were present at the first operation had been absolutely and completely removed. The cæcum was now readily manipulated, and it was found open, as supposed, at the site of the appendix, which had unquestionably sloughed off; the fistula was of sufficient size to admit the end of the little finger. This was closed with nine Lembert sutures; recovery was rapid and perfect.

As a result of repeated attacks of appendicitis extensive adhesions may surround the intestines also and cause fatal obstruction, as illustrated in the following cases:

PERICÆCAL ABSCESS. OPERATION REFUSED.
PLASTIC PERITONITIS. DEATH.

In the spring of 1890 I saw, in consultation with Dr. Trautman, of Philadelphia, a young man of 28 years of age, who had been confined to bed for a week, with all the symptoms of violent appendicitis. There was no defined tumor, but indistinct local hardness and general tumefaction. Temperature slightly raised; there was constipation, and pain, which was marked, was increased on pressure. There was also a history of several, perhaps three, former attacks, but not so severe as this one. I advised a lateral section and removal of the appendix, which sooner or later, I judged, would perforate and probably excite general peritonitis. The patient declined the operation. He subsequently had two attacks, in May and July.

Early in the following fall, the patient sought admission into the German Hospital. It appears that he was then suffering from another attack similar to the one in which I saw him. The trouble was at first supposed to be a retro-peritoneal sarcoma; then it was taken to be chronic peritonitis. He died of exhaustion, with symptoms of obstruction. The autopsy revealed an extensive, adhesive, or plastic peritonitis. The intestines, stomach, liver, spleen and bladder were so united as to form one huge mass, which, when loosed along the vertebral column, was lifted out entire; the appendix, which was undoubtedly the source of the trouble, was found firmly adherent to neighboring loops of intestine, with much inflammatory tissue.

The following case occurred very recently:

OBSTRUCTION OF THE BOWELS, PERSISTENT VOMITING. PURULENT PERITONITIS; SECTION; EXTENSIVE ADHESIONS FROM PREVIOUS ATTACKS OF APPENDICITIS; GANGRENE WITHOUT PERFORATION OF THE APPENDIX; DEATH ON THIRD DAY.

Mr. J. E., 32 years of age, living in Philadelphia, on January 21, 1891, was awakened early in

the morning by violent pain in the abdomen, referred to umbilicus and right inguinal region, with persistent vomiting. Bowels constipated, but had a small passage on the 20th. He had a similar attack last October, while away on a hunting trip, by which he was confined to bed for seven days. He then returned to his home, and was confined to his bed for some time with similar symptoms, from which he gradually recovered. In December he had another attack. He stated, however, that he occasionally had pain in the appendix region, especially when stepping out of his carriage or when his body was jarred, impressing him with the fact that everything was not right. He had had a similar attack in 1887. I was called in on January 22, by Dr. Woodbury, who had first seen the case the day before and had given him a cathartic and large enemata, without succeeding in evacuating his bowels. (His family medical attendant, Dr. Hetzel, was present, and agreed with us as to the necessity of laparotomy.) The operation was performed the same afternoon, by lateral incision. Pus escaped from the peritoneal cavity, showing commencing general peritonitis. The appendix, which was firmly adherent its entire length to the cæcum, was found with some difficulty. It was gangrenous, and tore while being examined. A ligature was thrown around it near the cæcum, and the very large, swollen organ removed. It was the largest I have ever seen. A glass drainage-tube was introduced deep into the pelvis, and small doses of calomel and soda given to check vomiting and move the bowels. There was so great prostration that further examination of the condition of the intestines could not be made. The pain and other symptoms of peritonitis immediately ceased and did not return, but the bowels could not be made to move. The patient vomited all nourishment, even water, and died exhausted on the evening of the 24th day of January.

The several attacks of peritonitis had resulted in general plastic exudation of the bowels, which caused the fatal obstruction—the final abscess, due to gangrene of the appendix, being only an incident in the final result. The operation should have been performed at an earlier period in the history of the attacks and before the occurrence of the extensive adhesions, when the disease was simply appendicular.

PART II.

TREATMENT AND TECHNIQUE OF OPERATION.

First Group: The treatment of the first group of cases, the irritative, catarrhal, or simple inflammatory disorders of the cæcum and its surrounding, or of the appendix, should consist in absolute rest in bed, the application of hot poultices or fomentations, perhaps local depletion, and possibly the hypodermic exhibition of morphine to control pain. The bowels should be kept open by the administration of calomel, or salines and enemata.

The diet should be restricted to nourishing liquids.

Second Group: In this variety of cases the disease is no longer simply irritative, catarrhal or inflammatory, but there is ulceration, with impending perforation, if the latter has not already occurred. Lymph, as a result of the violence of the disease, has been thrown out, which has either partially or completely enveloped the appendix, or this lymph exudation may have formed a wall sufficient to protect the general abdominal cavity when perforation and abscess have occurred. Perforation means pus and abscess; the diagnosis, therefore, of such a condition calls at once for abdominal section and removal of the appendix.

In a paper which I read more than a year ago, before the College of Physicians of Philadelphia, on inflammation of the vermiform appendix, I stated that "when the abdomen is believed to contain pus, whether intra- or extra-peritoneal, encysted or diffused, the rule of surgical procedure now is to make a section, remove the offending organs or the sloughing tissues of pus, thoroughly cleanse the surroundings and drain." This rule still holds good, and is being constantly followed with the happiest results.

The risks of operation at this time, are much less than those which threaten the patient. Early interference will save most if not all cases, while the danger of operation is slight as compared with that of general abdominal inflammation. The surgeon should never be satisfied in merely opening the abscess, which is simply a result, and not the cause of the trouble; if this only is done, the operation is incomplete, and at any time may have to be repeated.

Third Group: Here we have sudden perforation or sloughing of the appendix; in these cases there is no lymph wall separating the pericæcal surroundings from the general abdominal cavity, nor has the appendix been enclosed in lymph exudation—so that when the perforation occurs, the sloughing tissue, pus, and contents of the appendix are at once brought in contact with the general peritoneum.

The symptoms are at once profoundly grave, indicating general peritonitis and early collapse. Immediate section, removal of the appendix and cleansing of the abdominal cavity and contents, is demanded.

It is hardly necessary to say that the usual precaution in regard to cleanliness and rules of strict antisepsis should be observed. Generally, from the very nature of the case, there is but little time for any special preparatory treatment, prior to the operation.

OPERATION.

In my papers on the treatment of pericæcal inflammation, read before the Philadelphia County Medical Society, in December, 1889, and again in January, 1890, before the College of

Physicians, I stated that the line of abdominal incision should be lateral, and not median. The reasons for this statement are very obvious and positive; for, if the median incision be made, the peritoneal cavity would often be needlessly opened, while the cæcum and appendix can not be well reached or dealt with through it. But if the lateral incision is done, it can be made of less size, more circumscribed, and all the necessary manipulations can be made upon the cæcum, appendix, and surrounding parts without necessarily opening the peritoneal cavity. Should the abscess have reached the cavity of the peritoneum, the intestines can just as well be examined and cleansed through a lateral as a median incision. The incision should ordinarily be from three and a half to five or six inches in length. Starting from about an inch or so above the middle of Poupart's ligament, and to the outer side of the right line a semi-lunaris, it should extend upward and outward and directly over the appendix region, and be continued down until peritoneum, cæcum, or pus cavity is reached. The normally placed appendix, as I first pointed out, can always be found immediately under a point two inches distant from the right anterior superior spinous process, on a horizontal line drawn from this process towards the median line of the body. In some cases where the peritoneum is reached, its discoloration shows that it covers a pus cavity; in others, after the peritoneum is opened, not only pus but a lymph tumor enclosing the appendix, is found; this mass must be opened before the organ be dealt with.

Occasionally, when the abscess is cleansed, the appendix will be seen loosely floating, but frequently it is more or less attached to the cæcum, sometimes firmly fastened to it and detached with difficulty. Now and then it has a mesentery of its own, which may extend its entire length; this must first be tied in sections and then cut away: the appendix is then ligatured with catgut, or silk, close to its cæcal attachment and cut off. There is no advantage in invaginating the stump; in most cases, indeed, this treatment would really be impossible on account of the swollen, infiltrated and unyielding condition of the organ. In such cases there is no reason why the ligatured stump should not be allowed to project from the cæcum. The abscess cavity must slowly fill up and close by granulations. If the general peritoneal cavity has not been involved, the abscess walls and surroundings need only be washed out with hot water (or with 1 to 2,000 mercuric solution). If the appendix has sloughed, or even simply is perforated, search should be made for any foreign body, and all sources of further trouble gotten rid of. A glass drain should be placed in the most dependent part and the wound closed with a few stitches. Very commonly, however, the peritoneum is

found invaded by pus, so that the whole abdominal cavity needs to be thoroughly drenched with hot distilled water (105° to 110°). In such a case even greater care should be taken to find any foreign body which may have escaped from the appendix.

When the general cavity has been involved, a glass drain must be carried to the bottom of the pelvis in the hollow of the sacrum, a large rubber drain should also be placed in the superficial or cæcal abscess cavity.

The post-operative treatment is simple; it consists in the hypodermic use of small doses of morphia to relieve pain, while the ordinary rules of abdominal surgery are to be observed. No food need be given, by mouth, for the first twenty-four hours, or even longer. Nutritive enemata of beef tea, with or without whisky, can be administered every three hours with advantage. The bowels should be opened as early as possible, and for this purpose, small doses of calomel, one-sixth or one-tenth of a grain should be given half hourly, with an occasional one-eighth or one-tenth grain dose of podophyllin. When the bowels have acted, they should be kept in a fairly soluble condition by salines; even threatening peritonitis should be met by saline purgation.

The drain tubes may be removed as soon as the discharges are perfectly sweet, and reduced to a minimum. After recovery, the site of operation should, for a time, be supported by a flat, thin buckskin pad, kept in position by a broad band around the body, in order to avoid the occurrence of hernia.

PROPHYLACTIC TREATMENT.

This paper would be very incomplete, and I should not do justice to the subject, if I close my remarks without referring to the mooted question of the removal of the appendix in the interval between acute attacks. In fact, I have long urged, indeed from my first writing on this subject, that recurring attacks of appendicitis should be an absolute indication for the removal of the appendix at this most convenient time. When we remember that the appendix, which has been the subject of former attacks of disease, is liable at any time to be involved in that most dangerous of acute affections, perforation of the organ and pericæcal abscess, and when such a seizure may take place where adequate medical skill cannot be had, it seems much safer to avoid the possibility of future trouble from this source, by getting rid of the appendix when its surroundings are free from active irritation. Objection is made, and very naturally, to such a radical operation as excision of the appendix, especially when the patient is in a favorable condition or has apparently recovered.

If, however, health has become impaired by one or more attacks of mild or serious seizures, and if these attacks have increased in fre-

quency, severity, or duration, the removal of the organ is clearly indicated. The premeditated operation permits the careful preparation of the patient. The incision should be made in the same line as previously described, but it need not be more than three inches in extent. All bleeding points should be ligatured with fine catgut, when the peritoneum is reached, and after the wound is quite free from blood or other fluid, the peritoneum is incised. The omentum or intestine will then present itself in the wound; rarely will the appendix be seen until the bowel is pressed aside to the right with the finger. It may be found partially or entirely attached to the cæcum or elsewhere; if so, the adhesion may be separated by the finger, and divided between double ligatures. The appendix may be quite free from mesentery, or, as I often observed, it may extend throughout its entire length; should this be the case, the meso-appendix is ligatured in portions and then cut through between the ligatures and the appendix; the latter is then cut off near its cæcal origin. If the stump be permitted to remain projecting from the cæcum, free it must be included in a ligature, and its extremity covered by peritoneum.

I originally, in 1889, called attention to the fact that the stump of the appendix could be readily inverted and completely invaginated into the cæcal cavity, hence all danger from it could be gotten rid of. The manipulation consists in grasping the stump with a forceps or probe, and pushing it into the cæcum; the peritoneum is then approximated over the inverted stump by four or five sutures, which retain it in the cæcum, and effectually prevent its subsequent prolapse. This having been accomplished, the peritoneum is then brought together by a row of interrupted deep sutures, and also the external muscle and skin. Drainage could only be required in very exceptional circumstances. The after treatment is simple; the bowels having been well opened before the operation, need not be disturbed for several days; the dressings may go untouched for a week or even longer, when the sutures should be removed.

IN CONCLUSION.

I have thus gone over, somewhat briefly, the subject of this paper, and have also presented some of the difficulties which I have experienced; such difficulties, however, can generally be overcome. The key to the situation is the diagnosis, which should lead the way to prompt surgical treatment; and finally, if I have not presented anything specially new or interesting, I hope at least that the discussion of such an important subject will prove to be not without some practical value.

THE ELECTRICAL TREATMENT OF FIBROID TUMORS.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 5-8, 1891.

BY G. BETTON MASSEY, M.D.,
OF PHILADELPHIA, PA.

The progress of the Apostoli method of treating fibroid tumors of the uterus, presents both analogies and contrasts to those of some of the recent therapeutic claims that have been widely investigated by the medical world. Recognized at last, owing to the persistent agitation of its originator, it was, like the Brown-Séquard and Koch theories, enthusiastically adopted by those pioneer advocates who often make up for crudeness of training, and inexactness of observation, by a debt of stimulated progress laid upon subsequent workers. In contrast to the theories alluded to, it has since borne the test of capable experiment to an extent that even exceeds the original claims, and with the broadened use of electricity in other allied conditions, has made a new departure in gynecology. Unlike them also, it has encountered an opposition of unparalleled fierceness, an opposition, however, that has been as healthy as it has been fierce. The cause of this unusual attitude towards a new remedy is easily seen in the recent extension of abdominal surgery, and this highly favored disease has, therefore, been treated to a rivalry of methods that cannot be other than productive of the best results. Far from regretting this rivalry, I indeed point to it as an important index of medical development, and cannot but regret that other therapeutic efforts, now blindly accepted, are not subjected to similar tests. I do regret the intemperate statements of certain extreme opponents. Undermined in their wholesale and indiscriminate resort to dangerous operations, by the attention bestowed upon a milder and non-dangerous method of enforced atrophy, they have been invariably the aggressors in controversy, condemning in unmeasured terms a method of which they knew nothing. This is in striking contrast to the position of many electrotherapists, who willingly concede to surgery, certain cases unsuited to electrical treatment, yet demanding active help.

Experience is alone the final arbiter, and in view of the many cases of symptomatic cure and reduction, and the considerable number of those that have completely disappeared under electrical treatment, now on record, it is in order for those who advocate an exclusively surgical treatment to come forward, not with wet specimens just removed from patients who may die subsequently, nor even mere reports of deaths and recoveries from the operation, but with full reports of the ultimate results of each case that withstood the operation of oöphorectomy or hysterectomy.

The profession is not simply interested in the average mortality of these operations for comparatively benign tumors, but wishes to know also the results in the restoration of health and comfort to these patients. For instance, some careful operator should tell us how often removal of the appendages for bleeding myomas fails to control the hæmorrhages; how often this procedure in patients approaching the menopause is followed by mental disturbances; how often a successful hysterectomy is followed by abdominal fistulæ, intestinal adhesions, hernias, and other sequelæ that are as troublesome and painful to the patient as the benign tumor itself? Until such statistics are collected there can be no true comparison of surgical and electrical methods, as the latter refers only to results that are always more or less remote from the remedial procedures.

As an illustration of the results of the electrical treatment of these growths, I have arranged in a tabular form the histories of forty-six consecutive cases treated by myself, giving concise statements of the conditions present at the beginning of treatment, the nature of the applications, and the results as ascertained at various periods after the cessation of treatment.

An analysis of this table will show that seven cases should be eliminated from consideration in this paper, because two cases (Nos. 37 and 46), were polypoid, and their delivery was merely assisted by the electrical applications made, and five cases (Nos. 2, 14, 18, 21, 45), were treated for so short a period that it is impossible to use them in demonstration.

The remaining thirty-nine cases had more or less thorough treatment, and in the matter of results attained are divisible into five classes:

Class 1. Cases of complete anatomical and symptomatic cure, the tumor disappearing and the patient being restored to health. Of this class there were five (Nos. 7, 17, 20, 22, 24).

Class 2. Cases in which the tumor was considerably diminished in size and all other symptoms were cured. Of this class there were twenty-three (Nos. 1, 4, 5, 6, 8, 9, 11, 15, 16, 19, 27, 28, 29, 30, 32, 34, 35, 36, 38, 39, 40, 41, 42).

Class 3. Cases in which the tumors were not diminished in size, but all the symptoms were relieved. Of this class there were eight (Nos. 10, 13, 23, 25, 26, 31, 43, 44).

Class 4. Cases in which the tumors were not diminished nor the symptoms relieved. Of this class there were two (Nos. 12, 33).

Class 5. Cases made worse by the treatment. Of this class there was but one (No. 3).

PERCENTAGES.

Based upon the thirty-nine cases of thorough treatment, therefore, it will be seen that 12.8 per cent. resulted in complete cure and disappearance

HISTORY OF FORTY-SIX CASES TREATED BY ELECTRICITY. BY DR. G. BETTON MASSEY.

No. of Case.	Description of Growth.	Age of Patient.	Known Duration of the Growth.	Clinical Symptoms.	Method of Treatment.	Total Duration of Treatment.	Results.	Time after Cessation of Treatment, when results were Verified.
1	Sub-peritoneal, loosely attached hard growth, size of goose-egg, accessible through right vault of vagina.	45	4 years	Pressure on bladder and menorrhagia.	Buried puncture—60 to 200 ma. four times at intervals of a week.	1 month.	Complete relief of all symptoms and reduction of growth about one-third.	3 years.
2	Intra-mural and sub-periton'1 multilobular growth filling abdomen to four inches above umbilicus.	47	20 years.	General pressure symptoms and impairment of health.	Intra-uterine—100 to 200 ma. 12 days eight times daily.	12 days	Temporary aggravation of the pain due to frequency of treatment; subsequent improvement.	1 year.
3	Sub-mucous, sessile fibro-cyst, enlarging uterus symmetrically to size of 7th month of pregnancy.	49	5 years	Bloody and watery discharge, pain, and general impairment of health.	Intra-uterine—and plus 25 to 300 ma. every other day until os dilated and tumor presented.	3 months	Septicæmia occurred during expulsion of tumor, followed by death on the twelfth day.	
4	Sub-mucous, sessile polyp, of small size. Uterus hypertrophied; cavity four inches.	38	2 years	Pain and purulent leucorrhœa.	Intra-uterine—and plus 40 to 150 ma. ten applications.	3 months	Relief of symptoms, reduction of tumor to a nodule, and of uterus to normal size.	
5	Intra-mural, multinodular growth, filling abdomen and extending two inches above umbilicus.	38	2 years (?)	Profuse and hastened periods; severe pain and difficult locomotion.	Intra-uterine plus—and 65 to 150 ma. at intervals of week or more.	150 4 1/2 months	Symptomatic cure, restoration of menses to normal, and reduction of growth to two inches below umbilicus (about one-third).	1 1/4 years.
6	Sub-peritoneal and intra-mural multinodular growth, extremely hard, filling pelvis and lower third of abdomen.	41	12 years.	Constant pain, aggravated at periods which were of two-week type and profuse. Offensive purulent leucorrhœa.	Intra-uterine, 60 to 200 ma.—twice weekly; later, once weekly.	9 months	Arrest of all pain and discharge; reduction of tumor about one-fourth, and restoration of periods to 28-day type.	2 years.
7	Intra-mural growth, filling pelvis, with sub-peritoneal projection reaching the crest of the ilium.	34	9 months	Constant pain in left groin, and on walking, with profuse purulent leucorrhœa.	Intra-uterine—50 to 150 ma. twice a week.	8 months	Disappearance of tumor and of all symptoms, and reduction of uterus to normal size. Bands of adhesion left.	1 year.
8	Intra-mural, symmetrical fibroid of large size, wedged in pelvis, and extending to umbilicus.	40	1 1/2 years.	Severe pain, inflammatory attacks, pressure symptoms and impairment of health.	Intra-uterine—80 to 250 ma. every other day, and later every fourth day.	5 months	Quick release upward into the abdomen, with improvement of health; subsequent reduction to two inches below umbilicus (2/3).	2 1/4 years.
9	Intra-mural nodule, 2 inches in diameter in posterior wall of retroflexed uterus.	42	1 year.	Pain and other pressure symptoms, with menorrhagia and profuse purulent leucorrhœa.	Intra-uterine—50 to 125 ma. twice weekly, with intervals of non-attendance.	4 months	Symptomatic relief and considerable shrinkage.	3 months.
10	Intra-mural growth, size of small orange, in retroverted uterus.	33	2 months	Flooding two weeks at each period, with constant pressure symptoms.	Intra-uterine plus 25 to 100 ma. twice a week, with intervals of non-attendance.	8 months	Menstruation regular, lasting five days. Pressure symptoms relieved; no note of change of size.	
11	Intra-mural growth, size of fist, in right side of fundus; cervix elongated; syphilitic history.	30	1 year.	Hæmorrhages at periods which are irregular and frequent; profuse leucorrhœa and painful locomotion.	Intra-uterine plus 35 to 100 ma. once a week, with intervals of non-attendance.	6 months	Menstruation regular and painless; relief of pain and slight reduction in size.	
12	Two sub-peritoneal pediculated growths, sizes of large orange and lemon, separately attached.	36	1 year.	No Symptoms.	Intra-uterine, 30 to 50	3 months	No change	3 months.
13	Sub-mucous fibroid, size of large adult head, attached by broad base. Os admitting two fingers; growth rapid.	48	6 years.	Continuous hæmorrhages, with pain and impairment of health.	Intra-uterine plus and — 70 to 250 ma. every third day.	2 months	Arrest of bleeding and menstruation for 3 months. Subsequent history unknown.	
14	Intra-mural fibroid, size of small lemon, in anterior wall. Perimetrial adhesions.	25	2 years.	Irritable bladder, pain in back and difficult locomotion.	Intra-uterine—35 to 50 ma. twice a week.	1 month	Relief of symptoms; no record of change in size.	
15	Intra-mural, size of lemon, in posterior wall of retroflexed uterus. Tumor in Douglas' pouch.	40	3 years	Severe pain, pressure, profuse bleeding, menorrhagia and profuse leucorrhœa. Menstrual type, 21 days.	Intra-uterine plus 50 to 125, twice a week.	2 1/2 months	Arrest of hæmorrhage, restoration of menses to 28-day type, and slight reduction in size.	1 month.
16	Intra-mural growth filling pelvis. Uterus retroverted. Syphilitic history.	28	3 years	Hæmorrhagic periods and constant pain.	Buried puncture—200 ma. three times, and intra-uterine plus 50 to 100 ma. once a week.	6 months	Relief of pain, regulation of menstruation, and considerable reduction in size.	6 months.
17	Intra-mural growth, filling pelvis and extending above level of upper spines of ilium.	34	2 years	Profuse hæmorrhage and impairment of health.	Intra-uterine plus 60 to 110 ma. twice a week.	2 months	Total disappearance of tumor. Uterus normal in size. Hæmorrhage arrested. Menstruation normal.	3 months.
18	Intra-mural growth, the size of an orange, in anterior wall.	23	Unknown.	Excessive menorrhagia and anticipated periods. Very tender in hypogastrium.	Intra-uterine plus and — 30 to 70 ma. once per week.	1 month	No record. Case lost sight of	

19	Sub-peritoneal nodular growth, filling abdomen and extending to ribs. Treatment confined to a nodule in Douglas' pouch smaller and firmer. Pressure symptoms lessened and bowels move more freely.	60	4 years.	Pressure symptoms, affecting rectum and bladder especially.	Intra-uterine plus and — 50 to 100 ma., 10 to 15 minutes, depth of half an inch, six times.	1 month	Nodule in Douglas' pouch smaller and firmer. Pressure symptoms lessened and bowels move more freely.
20	Intra-mural enlargement of fundus of uterus to a size that fills the pelvis. Antimetrical, firmly adherent. Cavity, 3½ fibroid, size of large coconut, in posterior wall.	30	6 years.	Hemorrhagic periods, twenty-one day type with menorrhagia and tenderness.	Intra-uterine plus 60, followed by neg. vag. 40. The first treatment caused prolonged hemorrhage and pain.	1 month	No sign of tumor except lumps in tubal region. Uterus normal in size and movable; no pain. Periods regular.
21	Intra-mural, globular, fibroid, size of large coconut, in posterior wall. Cavity, 4 in.	40	2 mos. (?)	Constant hemorrhage and pain. Bladder irritable.	Intra-uterine plus 30, four times.	1 week.	Disappearance of pain.
22	Intra-mural growth, size of goose egg, in left wall, extending above level of true pelvis in anterior wall.	40	1 year.	Pain, fever, irritability of bladder, and irregular menstruation.	Intra-uterine plus 30 to 60 ma., five times.	1 month	Complete disappearance of projection 1½ months, and symptoms.
23	Intra-mural growth in anterior wall, size of small coconut, rising to the upper level of iliac bones.	45	Unknown.	Hemorrhage and pain.	Intra-uterine plus 20 to 80 ma., six times.	2 months.	Hemorrhage arrested by first application. Subsequent relief of pain. No record of change of size.
24	Intra-mural growth posterior and to left. Whole mass size of goose egg. Cavity, 3½ in.	41	2 years.	Immense loss of blood at periods, which return in 21 days. Pain and tenderness. General health impaired. Profuse leucorrhœa.	Intra-uterine 100 plus to 15 ma., twice a week, later once a week.	3½ months	Complete disappearance of growth, the cavity shrinking to 2½ in. Periods normal, without flooding or pain.
25	Intra-mural growth in anterior wall, nearly filling pelvis. Cavity, 3½ in.	36	14 years.	Flooding at periods, with pain, tenderness and leucorrhœa.	Intra-uterine plus 35 to 45, five times.	1 month	Flooding arrested and improvement of symptoms.
26	Intra-mural growth involving whole uterus, including cervix filling pelvis and extending to crest of iliac bones.	33	2 years.	Flowing every day for two years; no tenderness and no adhesions.	Intra-uterine plus 50 to 85 ma., once a week.	2 months.	Hemorrhage ceased after the first application.
27	Intra-mural growth, size of goose egg, in anterior wall.	40	2 mos. (?)	Pain and bladder pressure, with much local tenderness. Menstruation irregular. Leucorrhœa profuse.	Intra-uterine plus and — 20 to 50 ma., once a week.	1½ months	Complete symptomatic cure and reduction of tumor to the size of a walnut. The tumor is now sub peritoneal.
28	Intra-mural myoma, extending an inch above navel, with a cystic projection on right, containing "cells of Drysdale."	47	7 years.	Attacks of intense pain at periods, in which tumor swells, several times larger, impinging on ribs. No hemorrhage. Health impaired.	Intra-uterine plus and — 40 to 150 ma., twice weekly. Method changed to vagino-abdominal alternatives, 150 ma. after 3 months with aspiration of cysts.	1½ years.	Menstruation normal. Reduction of tumor to size of an orange and removal of all symptoms. No attacks for six months.
29	Intra-mural and sub-peritoneal projection from right cornua, reaching to 1½ in. of umbilicus. Cavity, 3½ in.	29	9 months.	Menstrual flooding every three weeks, with constant pain and tenderness. Menorrhagia.	Intra-uterine plus 25 to 70, once a week with intervals. Vaginal applications for a time.	13 months.	Relief of pain and restoration of normal flow. Tumor slightly smaller, more disengaged into abdominal cavity.
30	Intra-mural enlargement of uterus, with pedunculations to both sides. Electrode inserted 3½ inches.	44	12 years.	Menstrual cramps, requiring physician and morphia regularly. Flow lasts two weeks, and is profuse. Constant bleeding, lasting for months, requiring rest in bed; constant pain and tenderness; copious leucorrhœa.	Intra-uterine plus 20 to 60 about twice a week. Cramps followed treatment at first.	3½ months	Relief of pain and restoration of normal flow (5 days). Tumor distinctly smaller.
31	Intra-mural growth, size of large lemon, in left wall.	30	1 years.	Constant pain and tenderness; former attacks of bleeding; at present, pain and pressure symptoms.	Intra-uterine plus 20 to 30 ma., six times, with one — vaginal 100.	2 months.	Relief of pain, hemorrhage and leucorrhœa. No notes of change in size.
32	Intra-mural enlargement of uterus to size of child's head, extending to 3 inches below umbilicus.	46	2 years.	Pressure symptoms in moderate degree, with vesical interference.	Intra-uterine — and plus 20 to 70 ma., twice a week; later uterine alternatives 70 to 100 ma., once a week.	10 months.	Relief of all symptoms; reduction in size to five inches below umbilicus.
33	Sub-peritoneal growth, filling pelvis and extending to 1½ in. of umbilicus, attached by sessile pedicle to anterior of uterus.	45	6 years.	Bleeding periods and local tenderness, associated with bronzed complexion, anæmia and nervous prostration.	Vagino-abdominal alternatives, 150 ma., with occasional intra-uterine — 20 to 100. Puncture impossible owing to bladder.	5 months.	Release of tumor from pelvis upwards into abdomen. Results otherwise negative.
34	Intra-mural and sub-peritoneal multilobular growth, size adult head, extending to 2 inches of umbilicus.	45	4 years.	Retention of urine recurring frequently caused tumor to be diagnosed. Much pain in left leg.	Vagino-abdominal alternatives 100 ma., once per week. Intra-uterine treatment not well borne.	5 months.	Normal periods, great improvement in health and slight reduction in size.
35	Sub-peritoneal, sessile growth, extending from Douglas' pouch to below umbilicus. Narrow; movable.	50	Discovery recent.	Menstrual and menorrhagia at three-week intervals. Constant pain and weight. Leucorrhœa.	Barred puncture — 100 to 150 ma., every two weeks.	5 months.	Relief of pain and pressure on bladder and reduction to 1½ inches below umbilicus (about one-half).
36	Intra-mural projection, size of walnut, in posterior wall. Cavity, 3½ inches. Fibroid ovary on right side.	36	5 years.	Ex-sanguinated by excessive and long-continued hemorrhages.	Intra-uterine plus 30 to 60 ma., once a week at intervals.	6 months.	Normal periods free from pain at four-week intervals, with relief of weight symptoms and reduction of cavity to three inches.
37	Intra-uterine polyp, size of hen's egg, pedunculated.	52	5 years.		Intra-uter. faradic to extrude tumor without lacer. After expulsion it was removed by torsion of pedicle.	15 weeks.	Removal of tumor and restoration of health.

Age of Patient	Description of Growth.	Known Duration of the Growth.	Clinical Symptoms.	Method of Treatment.	Total Duration of Treatment.	Results.	When results were verified after Cessation of Treatment.
38	Sub-peritoneal mass filling pelvis and left side of abdomen to ribs, of uncertain attachment to uterus, extremely hard and firmly fixed. Intra-mural fibroid mass reaching to 1½ inches of umbilicus.	12 years.	No symptoms until a recent attack of bowel obstruction. Health poor.	Vagino-abdominal alternatives 125 to 150 every other day. Eminent consultant diagnosed probable sarcoma.	3 months.	Bowel obstruction cured; tumor loosened considerably and slightly lessened in size.	2 months.
39	Intra-mural fibroid mass reaching to 1½ inches of umbilicus.	3 years.	Lameness and dropsy of right leg from pressure. Pain and local tenderness.	Vagino-abdominal alternatives 80 to 125 ma., twice a week.	2 months.	Removal of lameness in two weeks. Arrest of menstrual pain and slight reduction in size.	Recent.
40	Intra-mural fibroid, size of large apple, in posterior wall.	15 years.	Local tenderness and pressure on bladder. Old history of hemorrhages.	Intra-uterine plus and—30 to 80 once or twice a month.	10 months.	Symptomatic cure and considerable reduction in size of tumor.	6 months.
41	Intra-mural growth, enlarging uterus to size of orange.	6 years.	Pain and profuse periods, which latter recur two and three times a month.	Intra-uterine plus 15 to 30 ma.	1 month.	Arrest of menstruation and cure of symptoms. Great reduction in size.	6 months.
42	Intra-mural growth in posterior wall, filling pelvis, and extending 2 inches above symphysis.	6 years.	Pain and profuse periods. Bladder much affected by pressure.	Buried puncture—250 to 60 ma. six times, and intra-uterine plus 35 to 60 ma. once a week.	9 months.	Partial relief of pain. Tumor reduced to a size that does not project above symphysis.	Recent.
43	Intra-mural and sub-peritoneal growth, filling abdomen to 1½ inches above umbilicus. Syphilitic suspicion.	12 years.	Pain and profuse periods. Locomotion painful.	Buried puncture—200 to 60 ma., and intra-uterine plus 30 to 50 ma. weekly, at intervals.	1 year.	Relief of pain. Menstruation regular and less free. Tumor reduced to half inch above umbilicus.	Recent.
44	Intra-mural growth, size of sweet potato.	15 years.	Pain, profuse and frequent periods. Was opened for diagnosis by a surgeon three years before.	Vaginal plus 30 to 100 ma. twice a week.	1½ months.	Cure of symptoms. No change in size.	6 months.
45	Intra-mural nodule in anterior wall, doubling the lateral diameter of fundus.	6 months.	Incontinence of urine, pain and tenderness.	Intra-uterine—23, twice.	1 week.	Complete cure. Tumor delivered.	6 months.
46	Sub-mucous growth, enlarging uterus to fill pelvis, and reaching to ½ in. of umbilicus.	7 years.	Profuse bleeding constantly for several years. Now nearly exsanguinated. Much pain.	Int.-uter. plus 60 once arrested hem. somewhat. Five mos later a 5-lb. tumor was delivered per vaginam.	1 week.	Complete cure.	6 months.

of the tumor; 79.4 per cent. in symptomatic cure with or without reduction in size; 5.3 per cent. were unaffected; and 2.5 per cent. were made worse. In other words, about 92 per cent. were successes and 8 per cent. failures.

THE COMPLETE CURES BY ABSORPTION.

Of the five cases of this, the first class, all were intra-mural in situation, and all were treated by intra-uterine applications.

THE CASES SYMPTOMATICALLY CURED AND ANATOMICALLY REDUCED.

Of the twenty-three cases of this class fifteen were intra-mural, four sub-peritoneal, three intra-mural and sub-peritoneal, and one sub-mucous.

THE CASES SYMPTOMATICALLY RELIEVED WITHOUT ANATOMICAL REDUCTION.

Of the eight cases of this class, six were intra-mural, one intra-mural and sub-peritoneal, and one sub-mucous. Six of these cases were placed in this class because, being dispensary cases and difficult to find, no record of their condition could be secured after their pains had been relieved and they had ceased attendance. It is possible that reduction in size has since occurred in some of them.

THE FAILURES.

Two cases were materially unaffected by the treatment, and one was made worse. The two were Nos. 12 and 33. No. 12 was that of a patient who had two movable, painless, sup-peritoneal growths attached to the uterus by long pedicles. There were absolutely no symptoms of these tumors beyond the physical fact of their presence, and as they were not situated favorably for electro-puncture and were giving no trouble anyway, they were left alone, after thorough trial of mild intra-uterine applications. No. 33 was a large kidney shaped sub-peritoneal tumor attached to the anterior surface of the womb and lying between that organ and the bladder. As the bladder was spread out in front of it, fan-shaped, preventing puncture, resort was had to long continued vaginal alternatives; under these the tumor was released from the pelvis, but the patient was not sure that she felt any better.

The case made worse, No. 3, a large intra-uterine fibro-cyst, was treated by me early in my experience with these growths, and before it was pointed out by Apostoli that this form was liable to be made worse by electricity. The death from septicæmia did not occur until some time after the cessation of treatment, and during attempts to extract the mass surgically by piecemeal. At the autopsy the anterior wall of the uterus was found to have been punctured. This case bore a strong resemblance to one related by Emmet in his work on "Diseases of Women" (Case 39, page 587), in which death also occurred during attempts at extraction by piecemeal, and though

sent to me by an expert surgeon, was better adapted to treatment by hysterectomy than by any form of electricity.

METHODS.

It will be noticed that six cases were treated by puncture. The greater number of these punctures were of the kind that has been designated as "buried"—a variety of puncture that was originated by myself, and one that I think both more powerful and more safe than that described by Apostoli, unless the latter is extremely superficial. Unlike the Apostoli needle, which is only insulated by a movable sheath up to the point at which the puncture is made, my own needle is insulated by vulcanized rubber to within one centimeter of the end, with a view of preserving the track of the needle through healthy tissue from an electrolytic softening that would prevent immediate union. Punctures made in this way have been observed by me to heal in three days in spite of the use of 150 ma. at the point within the fibroid mass, while the older form of puncture may remain unhealed for a week or more.

No unpleasant reactions followed any of the punctures, which were sometimes exceeding an inch in depth; and while I do not say that any but those skilled in it should attempt this method, I do not hesitate to employ it myself in those somewhat rare cases that are adapted to it. None of the cases in which the tumor disappeared were punctured, but this was merely because their intra-mural situation neither required nor permitted it.

The intra-uterine method is certainly the method of choice, and with the elastic platinum electrode devised by me, or those of Martin, much of the risk of stiff-sounding is avoided. I have been disposed of late to increase the intervals between these applications to from five to seven days, interspersing one or more vagino-abdominal galvanic alternatives for their additional help.

These latter applications, which have been associated with the name of Danion, have a considerable value when neither of the two better methods are available. I have seen reduction occur during the use of this method in several cases, and can testify to its power over inflammatory exudates around these growths.

An important element of success in the electrical treatment of some fibroid tumors is persistence—a quality of value in many other forms of work.

CONCLUSIONS:

1. While an increasing familiarity with hysterectomy for fibroid tumors will doubtless render operators more expert in that work, and possibly lessen still further the mortality of the operation, accurate knowledge is yet wanting concerning the after histories of the cases re-

ported as successful, with special bearing upon the relief of painful symptoms, or their increase by the addition of post-operative incidents or accidents.

2. A conservative method of treatment which apparently acts by inducing retrogressive changes in the morbid process, resulting in a complete cure of over 12 per cent., and a practical cure of 74 per cent. of all cases, deserves most careful consideration from scientific men, since but few remedial measures for analogous diseases can lay claim to an equal measure of success.

3. The electrical method of arresting, reducing and dispersing fibroid tumors, besides being truly curative in transforming vitiated tissue action into natural absorptive processes, has the further merit of leaving intact all neighboring organs and functions yet existing, as the ovaries, etc., the current acting as a general revivifier of all highly organized parts and processes, while hastening the destruction of adventitious and lowly organized tissue.

TRAUMATISM OF THE CHEST.

Read in the Section of Surgery and Anatomy, at the Forty-second Annual Meeting of the American Medical Association, Washington, D. C., May 5, 1891.

BY J. MCFADDON GASTON, M.D.,
OF ATLANTA, GA.

In the course of my investigations on thoracic surgery for the *Annual of the Universal Medical Sciences*, I have been strongly impressed with the lack of knowledge in regard to the injuries of the chest. While this subject has been considered somewhat carefully in my two contributions to that work, there are many practical details of great importance which are not touched upon, owing to the paucity of data afforded by the very limited reports in this branch of surgical experience.

It is not my purpose now to enter into the minute distinctions of the lesions resulting from violence to the walls and contained viscera of the chest. I ask for the attention of surgeons to the great advantage of methodic treatment of traumatism of the chest.

All those inflammatory processes of a latent or idiopathic nature, which lead to serous effusions primarily or to suppuration secondarily, within the thoracic cavity, are excluded, as not germane to our present undertaking. In like manner, the very extensive lesions involved in operations for the relief of the above conditions in all stages do not come within the scope of this paper.

Foreign bodies entering through the trachea into the bronchi, and causing mechanical obstruction or inflammatory complications, call for consideration, from the general inflammatory impression transmitted to the pulmonary structure.

Blows upon the parietes of the thorax which propagate a shock to the lungs or heart, involving an impairment of function, or subsequent organic changes, come appropriately under the heading of traumatism, though no superficial contused wound is apparent.

Of course, all violence from without which produces injury to the structures within the chest, should be regarded as the proximate cause of the lesion, whether it be hæmorrhage, congestion or inflammation.

The grosser accompaniments or consequences of violence, consisting in notable contusion of the soft parts and fracture of the bony walls of the chest, are frequently the exciting causes of transmitted inflammation to the vital structures of the thorax.

Among the gravest injuries to the chest are the wounds by firearms and by cutting or puncturing instruments. These generally bring about the entrance of air into the pleural cavity, and thus, by pressure upon the corresponding lung, there is serious interference with the respiratory act. Should the pulmonary tissue be involved in the wound, there is likely to occur emphysema from the entrance of air into the areolar tissue of its parenchymatous structure, so as to effectually prevent the alternate expansion and contraction of the bronchial ramifications.

The former condition of pneumothorax may be a result of air escaping from the bronchial tubes when wounded, even when the external incision or puncture may be of a valvular nature which does not admit of the entrance of air from without.

If the external wound is patulous, the ingress and egress of air occurs with each act of expiration and inspiration, inducing the condition of traumatopneæa.

This is a most unpleasant result, and introduces a grave complication in the nature of the case.

There is also most frequently sanguineous extravasation into the pleural cavity from such injuries, and if the lung has not become collapsed from the entrance of air, its function of respiration is impeded, if not obliterated, by the blood pressure.

Should the parenchymatous structure be involved in gun-shot or punctured wounds of the lungs, there may be emphysema to a greater or less extent throughout the cellular tissue of the thorax and adjacent parts.

The constitutional or systemic effects of any violence to the thorax depends upon the amount of shock in the first instance, or the inflammatory process which is developed subsequently.

The greatest diligence on the part of the surgeon is requisite to avert the immediate fatal result of penetrating chest wounds. Apart from the general manifestations of chest wounds, there

are local effects from mechanical causes which require our consideration.

One of the most serious consequences of violence to the walls of the thorax is rupture of the lungs. A fall upon some solid body or the pressure of some heavy weight, while the lungs are greatly distended by closure of the glottis, induces rupture of the pulmonary tissue, with all the serious results of pneumothorax and hæmoptisis. This may occur even without an abrasion upon the surface of the chest; and the history of such an accident is the only explanation of the grave condition within the thorax.

A forcible impression upon the walls of the chest may fracture the sternum or ribs and drive either inwards so as to lacerate the lungs or the heart, leading to immediate or remote serious effects.

One of the grave consequences of an opening through the chest walls is the protrusion of a portion of the lung, constituting a hernia. If this should occur under the observation of a surgeon, he would find little difficulty in returning it and retaining it within by a compress. But most frequently it has been exposed for some hours and has become engorged, so that it is entirely impracticable to reduce it without enlarging the opening in the walls of the chest. This would seem the most feasible mode of relief if the vitality of the tissue had not been impaired by the constriction. But it is generally held to be safest either to allow the protrusion to remain and slough away, or to assist its detachment by placing an elastic ligature around the neck of the hernial tumor. The edges thus become agglutinated and the lung occluded. There may also occur laceration of the lesser or greater blood vessels of the thorax calling for prompt relief, if the injury does not prove immediately fatal.

It has been proven by subsequent observation of the effects that lesions of the heart have healed and that injury to the coats of the large arteries are not necessarily fatal. But there is no instance on record of a wound of the vena cava without a fatal result.

The thoracic duct, in like manner, cannot be wounded with impunity, and the escape of the lymph terminates in death.

While the ligation of the intercostal arteries, the internal mammary and the subclavian is attended with difficulty, the hæmorrhage from these vessels may be controlled, and the patient should not be abandoned to his fate. If blood has accumulated within, it may be withdrawn by suction, or its escape may be promoted by position.

Those who have had the largest sphere of observation in this branch of thoracic surgery will best understand the uncertainty hanging over pulmonary disorders resulting from violence.

Commencing with the doubts as to the production of traumatic pneumonia, and running through the abscesses of the parenchymatous structure of the lungs, it is remarkable how little is finally and definitely determined as a guide for practice in thoracic injuries. It will be found upon attempting to analyze the reports of such lesions that quite a variety of opinions are entertained by different observers, and that really no methodic treatment has been adopted generally by the medical profession. I know of no work on surgery which lays down fixed rules for the practitioner in the management of wounds of the chest.

The contributions to the literature of traumatism of the chest in Holmes' System of Surgery, Vol. I, in the International Encyclopædia of Surgery, Vol. II, in the Reference Hand-book of Medical Sciences, Vol. IV, and in the Annual of the Universal Medical Sciences for the years 1889, 1890 and 1891, represent fairly the status of this branch of surgery. Those who seek to keep abreast of the recognized data may learn from these works what has been accomplished for the relief of this class of injuries. It will be noted that there are conflicting views in regard to the proper treatment of some of the consequences of penetrating wounds of the chest, dependent, no doubt, to a great extent, upon the different standpoints from which observations are made. While there is a correspondence, for the most part, among different authorities in the propriety of closing the external opening in the wall of the chest, when the amount of blood in the pleural cavity is small, contradictory opinions are expressed when it is large.

To define more clearly the attitude of those who have written upon this topic, I may state that individual views of the nature of such injuries, with the steps recommended for their relief, rest very much upon personal observation, and not upon the consensus of general experience by the profession.

There are articles upon thoracic wounds in most of our standard works on surgery, presenting many points of a practical bearing, as viewed by the author, yet with such material differences in their application, under the emergency of treatment, as to avail little for the practitioner.

While we should not overlook the writings of former days, it may be stated that little progress has been made in the elucidation of wounds of the chest since the works of Gross and Agnew were presented, and some of the more recent authors, as Wyeth and Roberts, have touched upon chest injuries very briefly, while Senn ignores, with a few exceptions, traumatic developments of the thorax, in his principles of surgery.

Many important data, illustrating the results of gunshot wounds of the chest, are given in the Surgical History of the War, published by the

United States Government, and the statistics of non-penetrating and penetrating wounds of the chest therein presented, demonstrates the gravity of the latter as compared with the former in a most conclusive manner. This, however, only confirms the results of the records of military operations throughout the world, showing that about 1 per cent. of non-penetrating wounds of the chest prove fatal, while over 65 per cent. of penetrating wounds terminate in death at an early period after the injury.

One of the practical questions of greatest moment, in regard to the hermetically sealing of gunshot wounds of the thorax, remains unsettled.

Experiments upon the inferior animals, commencing with those of Houston in 1728, for illustrating the effects of punctures and incisions into the thoracic cavity, have been attended with such different results upon the lungs, that it is yet undetermined whether collapse ensues directly from the wounds. There is such an intimate relation of the surface of the lungs to the costal pleura, that something must separate them for the occurrence of pneumothorax, and hence it occurs that openings are not always followed by this result.

It is held that the falling away of the lung is not a uniform consequence of a penetrating wound of the chest. If the wound is small, or if it is at a distance from the free margin of either lobe, the expanded lung remains in contact with the costal pleura.

The adhesion of the two pleural surfaces is illustrated by an experiment of Surgeon A. H. Smith, in which, in a recently killed animal, an opening was made in an intercostal space midway between the sternum and the spine. The lung did not collapse; but on making another in the same intercostal space, close to the sternum, the outer surface of the lung was observed to slide backwards, though still remaining in contact with the chest walls, until the edge of the lobe came opposite the first opening. Then for the first time air entered here, and the pneumothorax became complete.

Gordon and McDonald found that with small tubes introduced into the chest, the breathing became quick and laborious, while the lungs had fallen away from the chest walls for an inch. After four minutes, they enlarged the wound and put in tubes whose united calibre was twice that of the glottis. The respiration became very laborious. On closing the wound, however, and applying friction to the chest, the respiration was restored, and in ten minutes the animal was able to walk about. It was killed on the fifth day and nothing notable was found in the chest.

Dr. Northrup reports some experiments on animals, contradicting the statements of Samuel West, that the force of cohesion sufficed to maintain the lung in complete expansion when the parietal pleura was punctured.

Further experiments were made, in which a dog's two pleuræ were fitted with double flanged canulæ, stoppered with corks. Until the dog recovered from ether, the two corks were left in place. When fully recovered one cork was withdrawn, and the dog scarcely suffered dyspnœa on moderate exercise. When both corks were removed the dog traveled about for two minutes and succumbed to severe dyspnœa, which again entirely disappeared on replacing the corks.

These results throw some light upon the practical resort to closure of the external openings into the pleural cavity as a curative measure in cases of penetrating wounds of the chest.

Howard's proposition to the Surgeon-General of the United States during the war, to test the process of hermetically sealing the external orifices of gunshot wounds of the chest, met with so much prejudice on the part of the surgeons of the Federal Army, that it was used in a limited number of cases. It is also inferred that the conditions under which this measure was tried were not favorable to its success, as the most grave cases were the subjects. Judging from my own experience of the good effects of closing penetrating wounds of the chest, and from the records of cases thus treated by others, it seems unfortunate that hermetically sealing was not applied on a larger scale, so as to afford the statistics for a final and conclusive decision as to its merits. Independent of the recognized advantages of closure in the lesser accumulations of blood in the pleural cavity, it is held by some, with a show of practical discernment, that in the most extreme cases of thoracic hæmorrhage, the flow of blood externally should be arrested by plugging the orifice, so as to favor the coagulation of the blood within, and by compression upon the lung to prevent further extravasation.

If this course is applicable in the most aggravated condition of penetrating wounds of the chest, as well as to the simpler form in which there is a slight hæmorrhage into the pleural cavity, why may it not prove serviceable in the intermediate accumulations of blood in the thorax, and thus be applicable to every variety of penetrating wounds of the chest.

It is not expected that a general rule can be laid down, without exceptions, for the immediate and complete closure of all penetrating wounds of the chest. There must be certain preliminaries observed in the preparation of the patient for receiving the benefits of such proceeding, so as to close the orifice with the least blood in the cavity of the pleura, that is possible. Placing the patient so that the opening shall be the most dependent part, with a firm bandage around the thorax, and making the occlusion immediately after the expulsion of air and blood from the wound by forcible inspiration, should promote a favorable result.

If the case is complicated with emphysema involving any considerable portion of the surface, plugging the orifice with a condom stuffed with sponges, as has been suggested for the arrest of hæmorrhage from an intercostal artery, will prove efficient in preventing the escape of air into the cellular tissue and at the same time accomplish complete occlusion of the thoracic cavity.

A comparison of this procedure may be made with that in which the air enters the cavity of the pleura and induces collapse of the lung, thus arresting the flow of blood from the wounded parenchyma, with a tube in the opening, as recommended by Packard, for prevention of emphysema. In this latter, the air pressure is supposed to arrest the bleeding. In the other condition, blood clot presses upon the lung so as to control the hæmorrhage.

The variable influence of the air in the pleura, with more or less air entering the lung by the inspiratory act of the sound side, renders this recourse very doubtful in permanently controlling the escape of blood from a wound of the lung.

On the contrary, the formation of blood clot within the pleura keeps up a pressure which can be relied on to prevent the further bleeding from the pulmonary lesion.

All those who have observed the relief of distressing dyspnœa by closing an open wound of the chest, concur in its great benefits.

It may be inferred from the favorable progress of cases in which a large accumulation of blood has remained in the pleural cavity, that its gradual absorption occurs. If the air is completely shut off from without, of course germs cannot enter to set up decomposition in the mass, even should there be a perforation of the bronchia, as it is held that air passing through this sieve-like structure is rendered innocuous.

With the larger death rate from penetrating wounds of the chest treated without special reference to the process of occlusion, the result is not likely to be more serious from a uniform adoption of sealing hermetically all external openings of penetrating wounds of the thorax.

If the worst consequence of this procedure ensues in purulent development, there is open to the surgeon such measures of relief as have been adopted successfully in empyema from other inflammatory processes.

In this connection, a few cases which have come under my observation, may serve to illustrate the open and closed methods of treating wounds involving the thoracic cavity.

Many instances of gunshot wounds of the chest were brought to my attention as chief Surgeon of Division, during the civil war in this country. But I had no opportunity of following up the subsequent course of those injuries; and would refer to reports of such cases in the Surgical History of the war for the results. I will give, how-

ever, an outline of some characteristic cases, occurring in my own private practice and in consultation with others, during the past few years.

One case had a pistol ball wound at short range between the fourth and fifth ribs, on the right side, in front, and ranging downward. All the physical signs were present, indicative of a wound of the right lung, extravasation of blood into the pleural cavity. It was kept open for a time, but closed afterwards spontaneously and terminated fatally.

Another case, in which a ball from a large Colt's revolver traversed the left side of the chest, entering through the lower border of the pectoral muscle and escaping between the ninth and tenth ribs near their cartilages, involved the pleural cavity. There was a discharge of frothy blood from the posterior wound and the physical signs of extensive sanguineous extravasation into the left pleural cavity. The heart was perceptibly pressed over to the right, carrying the apex beyond the median line. While no suture was used to close the wounds, they were hermetically sealed by antiseptic dressings, and notwithstanding considerable constitutional disturbance, subsequently the patient made a good recovery.

A third case was a child, accidentally shot, the pistol ball entering through the ensiform cartilage and ranging upwards. No precaution was used to close the wound, and the patient died from empyema.

The fourth case was from a pistol shot which entered just below the ensiform cartilage, ranging upwards to the right and lodging above the eighth rib, thus passing through the diaphragm and lower portion of right pleural cavity. The external hæmorrhage was not pronounced, but the presence of blood in the chest was inferred from the physical signs of dullness upon percussion, and diminution of the respiratory murmur under auscultation. There seemed to be no indication for occlusion of the external wound, and it was therefore left open. As there may have existed complications involving the abdominal viscera, the fatal termination on the fourth day cannot throw any light upon the true cause of death.

The fifth case affords an instance of a pistol ball entering the chest, immediately over the heart, traversing the mediastinum and lodging upon the sixth rib of the right side just behind the posterior axillary line. The external wound was occluded, and the ball was not removed until after the general shock and slight inflammatory reaction had passed off. The patient made a good recovery by the strict observance of masterly inactivity.

This case, with that preceding, having the ball lodged superficially for several days before removal, seems to emphasize the caution against cutting down and extracting a ball under such circumstances at the outset.

I recall in this connection, after the first Manassas battle, allowing a minnie ball, which was impacted in the clavicle and first rib, to remain, lest by its extraction the chest cavity should be exposed; but the final result of the case is not known.

The practice of removing balls lodged between ribs, which is inculcated in Agnew's Surgery, without proper limitation, is more honored in the breach than by the observance. It is evident that the immediate extraction of a ball from the border of a rib, after it has traversed the chest, must leave an opening into the cavity of the pleura and aggravate the gravity of the case.

A counter opening in the muscular structures for the removal of a ball which is near the surface, does not in the experience of surgeons of large practice, retard the healing process along the line traversed by the ball.

But with the conditions presented in a gunshot wound in the thorax, when an opening already has been made by the entrance of the ball, it is not good surgery to make another for the extraction, until the wall behind has become solidified.

In illustration of the effects of punctured and incised wounds of the chest, a few examples of knife stabs, which have occurred in my practice, will be added.

A case of stabbing, between the fourth and fifth ribs, in front of the anterior axillary line on the left side, was accompanied with localized emphysema. While there was evidence of sanguineous effusion in the pleural cavity, the bleeding was profuse externally.

There was slight dyspnoea upon lying down, which was relieved in the sitting posture. The wound was closed by adhesive plaster with a compress and bandage, and the patient recovered without an untoward symptom.

It has not been found necessary to use stitches in these wounds inflicted by the thrust of a knife blade, as the coaptation is effected by the above process, so as to hermetically close the opening in the chest.

In another case a stab was inflicted between the sixth and seventh ribs on the left side near the margin of the scapula, from which blood and air escaped at each inspiration, with considerable accumulation of blood in the pleura, and hæmoptysis. The external wound was closed immediately after a gush of blood and air from the opening. The patient became more quiet afterwards. This case was accompanied with traumatic pneumonia and marked constitutional disturbance, but ultimately recovered.

A third case came under my observation in which a knife blade entered between the fifth and sixth ribs on the right side, penetrating the lungs and attended with the accumulation of blood in the pleural cavity. There was no very marked dyspnoea, and as the flow of blood exter-

nally gradually diminished with the dependent position of the wound, it was not thought that closure of the opening was indicated. Inflammatory symptoms soon developed with subsequent adhesion of the pulmonary and parietal pleura. In the end, suppuration of the lung found its way through the external opening. A weak solution of carbolic acid was injected into the suppurating tract daily, and the healing process progressed favorably, so that there remained eventually but slight impairment of the lung from the injury.

The inference from these cases goes to prove that suppuration is more likely to occur when the incised wound is left open than when it is closed immediately and kept occluded.

A fourth case was seen some days after a stab had been inflicted between the seventh and eighth ribs, and there was a protrusion of a small globular mass of pulmonary tissue from the wound. As it had occurred shortly after the injury and was tightly constricted by the margins of the wound in the thoracic wall, the neck of the hernial tumor was encircled with an elastic ligature, as most likely to effect a prompt and safe detachment of the mass. In a few days it separated, and there was no further trouble with the case. If there was any escape of blood into the pleura it was most effectually shut in by the plugging of the opening, and afforded an illustration of the favorable issue of hermetical sealing in penetrating wounds of the thoracic walls.

IS 'EARLY RESECTION OR CONSERVATIVE TREATMENT ADVISABLE IN COXITIS?

Read in the Section of Surgery and Anatomy, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY HERMAN MYNTER, M.D.,

PROFESSOR OF SURGERY, NIAGARA UNIVERSITY, BUFFALO, N. Y.

While our increased knowledge of the pathology of tuberculous joint affections has resulted, in most joints, in earlier operations, in order to remove the local focus before the joint has become totally disorganized, the same cannot properly be said about tuberculous affections of the hip-joint. We still find the same disagreement between the adherents of conservative and operative treatment, and I scarcely say too much when I state that, in the vast majority of cases, excision is still made as *ultimum refugium* only. Yet even in these cases, a better knowledge of the pathology and consequently improved operative methods, have been followed by decreased mortality and improved functional results. In order to decide the question, it seems proper shortly to study the pathology of coxitis. We formerly believed that tuberculous affections of the hip, or, for that mat-

ter, of any other joint, commenced as diffuse inflammations, which went on to destruction of the joint. Post-mortem examinations were rare, except in cases which represented the later stages of coxitis. In these the synovial membrane was always found diffusely diseased, the ligaments and the perisynovial tissue changed to gelatinous, œdematous or fibrous tissue, the joint itself filled with fungous granulations, the cartilages generally ulcerated and shed, leaving the epiphyses in a state of softening and caries. But often we found the cartilages more or less intact, and we therefore believed that the synovitis was the primary lesion, the disease of bones and cartilages secondary. The tuberculous bacillus was unknown, and we supposed a dyscrasia present. Furthermore, all acute infectious diseases were known to be followed occasionally by inflammations of the joints, which always commenced as a synovitis, as in pyæmia, puerperal fever, typhus, scarlet fever, etc. It was acknowledged that the inflammation occasionally might commence in the bone, but it was believed that it even then commenced as diffuse inflammation of the medullary tissue in the epiphyses.

We overlooked that these diffuse processes, whether in bone or in synovialis, were secondary, and were the result partly of an infection, partly of reactive and reparative processes.

It is the Germans, particularly the late Prof. Volkmann and Prof. Kœnig, both of whom I quote extensively in this paper, to whom belongs the credit of proving that the fungous or tuberculous joint affections commence, in the majority of cases, as a local focus in the bone, and that the consecutive entrance into the joints of the *materia morbi* from the local focus produces the diffuse inflammation of the synovialis and the epiphyses. That the disease, in a few cases, may commence as a synovitis, is not denied, and is occasionally proved by post-mortem examination.

This is by no means a generally accepted theory. Habernern, for instance, states that in 132 cases of excision, a primary osseous lesion was present 80 times, 23 times a primary synovial affection, while the starting-point was doubtful in 29 cases. Watson Cheyne thinks the disease more often primarily osseous, although not in the proportion Habernern states. The trouble is that only in early cases can the presence of a local focus be shown. In late cases we find exactly the same changes in bones and joint, whether the disease started as an osseous or synovial inflammation.

It is, therefore, probably true that the vast majority of cases commence, as Volkmann says, as an osteitis and not as an arthrititis, and more particularly as a circumscribed cheesy or tuberculous osteitis or osteomyelitis.

It depends upon circumstances whether the joint later becomes attacked, viz.: whether the

products of the inflammation perforate into the joint, as usually, from anatomical reasons, occurs, or seek the surface. The primary focus, at least in childhood, is always in the bone, either central or near the periosteum. Generally only one focus is present, and it is rarely the case that both epiphyses are attacked simultaneously.

The focus is generally small, as large as a cherry-pit, or at most as a nut. The neck is the point of predilection, in the near neighborhood of the epiphyseal cartilage, or in the diaphysis or trochanter major, while the head is rarely the starting-point. The focus may perforate the epiphyseal cartilage in order to invade the epiphysis. It may even commence as a chronic osteomyelitis in the cavity of the femur, and work its way upwards. Primary attacks of the acetabulum are probably more frequent than generally believed. Habernern states that in his 80 cases, the acetabulum was attacked alone in 50 cases, the femur alone in 23 cases, and both together in 7 cases.

The focus presents itself as a little cavity filled with cheesy granulations and bone detritus, and frequently a sequestrum and surrounded with a pyogenic tuberculous membrane. Sequestra were present 51 times in Habernern's 80 cases, soft caseous deposits 29 times. If the focus perforates into the joint, tuberculous synovitis occurs, with very acute symptoms. If the focus is in the neck or trochanter major, the joint occasionally escapes, the osteitis and abscesses being extra-capsular.

While the osteitic process is going on in the neck and before perforation takes place, we may discover changes in the joint itself. The synovial membrane, the periosteum and the periarticular tissue become more or less infiltrated and œdematous, slight exudation may occur, and a partial obliteration of the joint may take place; little by little the whole synovial membrane may be changed into a granulation-tissue, and yet we have no tuberculous arthrititis. When at last the perforation occurs, it is into a half obliterated joint, and the symptoms are therefore proportionately less, as a joint reacts the more severely to infectious products when the synovial membrane is physiologically intact, and the less severely the more the synovial membrane has been changed into a granulation-tissue. This partial obliteration we meet particularly in the knee-joint, but less often in the hip-joint, where we consequently are more apt to meet acute suppurative arthrititis. Yet even here we occasionally see a central necrosis of the head and neck being followed by an obliteration of the joint, thereafter destruction of the epiphyseal cartilage and diastasis of the head, which meanwhile has become firmly attached to the acetabulum. As a rule, the hip-joint is attacked early, as the whole neck, in which the local focus generally is found, is inside the synovial capsule, but we may see the joint escape

even when the focus starts as a central necrosis in the head or neck. A carious fistula may then be found perforating outward through the trochanter major. This point is of importance, as indicating the way in which such a central necrosis may occasionally be attacked, through trephining of the trochanter and the neck or by ignipuncture.

The perforation of the tuberculous local focus having occurred into the healthy or half obliterated joint, farther pathological changes take place, while at the same time the symptoms of coxitis, which so far have been vague and insignificant, become pronounced on account of the implication of the synovial membrane, the cartilages and adjacent Haversian canals. The characteristic symptoms are particularly the starting pains and the muscular contractions, both indicating osteitis in the neighborhood of the joint cartilages, while the position of the limb (abduction, flexion and rotation) is less characteristic, probably depending upon other causes.

The pathological changes are those of a tuberculous synovitis with its resulting destructive processes.

The round ligament, which is covered with synovialis, is early attacked and softened, and then disappears.

The osteitic process generally commences at the place of insection of the sound ligament to the head and acetabulum, and on the neck at the place where the synovialis is attached. The cartilages become ulcerated by pressure of the granulations (Voikmann's Ulcerative Decubitus) or shed by pressure of the granulation-tissue, meanwhile developed in the dilated Haversian canals. The bones are now in a state of osteoporosis; the head loses its roundness and becomes smaller from pressure just as the acetabulum enlarges by pressure upwards and backwards, or becomes perforated by gradually developed decubitus, and spontaneous dislocations and intra-pelvic abscesses result. Peri-articular abscesses are rarely the result of the breaking down of granulation tissue in the peri-articular tissue. They occur usually from softening and perforation of the capsule itself. So much in regard to the pathology. Yet I wish at this stage to show a pathological specimen which to the fullest illustrates the pathological process as here described; the patient is a little girl of 10 years of age, who entered the Sister's Hospital in Buffalo in March, 1891. She had then been sick only two weeks, and a physician had opened an abscess on the outer side of the right femur. Contra-openings were made in the hospital and the abscess found to be situated beneath the vastus muscles, but apparently not connected with the hip-joint, which seemed healthy. Two weeks after entering the hospital she grew worse and offered the usual symptoms of coxitis. Under chloroform

the joint was examined and a carious process found on the upper side of the neck. A good sized abscess was found in the pelvis and opened. As this abscess was supposed to indicate perforation of the acetabulum, I removed the head and neck, which I here show. You see a local focus in the neck which had opened into the joint, the synovial membrane of which was found thickened and tuberculous. The round ligament had disappeared and at its place a carious process is going on. The cartilages are yet healthy. I suppose the carious process on the upper surface of the neck gave occasion to the first abscess, and that the tuberculous focus perforating into the joint produced the acute symptoms of coxitis. In this case the excision was performed about four weeks after the beginning of the disease. In another case, operated at the same time, the disease had lasted two months. I found there a sequestrum in the neck, three-fourths of an inch long, a perforation into the joint, shedding of the cartilage, osteitis of the epiphysis, diastasis of the epiphyseal cartilage and tuberculous synovitis. In both cases the operation cut short the disease, the wounds healed rapidly and the final result will be what I have always obtained, a movable joint with some shortening, which is easily overcome by aid of a thick sole. I consider this specimen of peculiar value as showing the condition in the early stage. In later resections, in which we find diffuse osteitic processes of head, neck and trochanter major, destruction of cartilages and tuberculous degeneration of the synovial membrane, it is impossible to find the local focus, as everything is diseased, but that does not prove that it was not present in the start.

Coxitis may under favorable conditions, terminate in recovery in any stage, of course with more or less deformity, and the usefulness of the limb depends upon the amount of flexion and adduction. A perfect recovery with normal joint is rarely obtained. I myself remember only one case. And with what cost is this imperfect recovery with a more or less deformed limb, obtained? It means years of suffering and treatment, be that with extension in bed or with a portable apparatus, frequent operations for abscesses with resulting fistulas, the dangers of amyloid degenerations of liver and kidneys, and of tuberculous meningitis, and lastly of an excision as *ultimum refugium*, at a time when neither the broken down constitution of the patient nor the extensive destructive processes in head, neck and shaft favor reparative processes. In those cases in which we do not have an abscess, the tuberculous focus has probably become incapsulated, surrounded with a zone of sclerotic bone tissue, and the synovial membrane is not tuberculous, although the joint may be partially or totally obliterated. In these cases conservative

treatment is probably indicated. But if abscess is present, it shows that perforation has occurred and in my opinion an early operation is the only thing that can arrest the disease.

And yet, why wait for abscess? The tuberculous bacillus, as is well known, is not a pyogenic bacillus and may under favorable circumstances continue to grow and infiltrate surrounding or more distant tissues. If abscess occurs, the pyogenic bacterias, particularly the staphylococcus pyogenes aureus, will always be found present as the cause of the suppuration. The chronic pathological process has only become complicated by the acute suppuration, and the tuberculous process keeps up advancing simultaneously with the suppuration.

It must not be forgotten, that the statistics of resection must be compared with the statistics of those conservatively treated cases, in which abscesses were present. In both classes we find a great decrease in mortality in one time.

Leisrink, for instance, gives a mortality of 63 per cent. after resection, of which 22 per cent. succumbed to wound complications, 21 per cent. to marasmus, 11 per cent. to phthisis, 7.5 per cent. to amyloid degenerati, etc. A more recent English statistic of 320 cases showed a mortality of 40 per cent. Jacobson has increased Leisrink's statistics of 176 cases to 250 cases and finds a mortality of 40 per cent. The result of conservative treatment was even worse. Of 63 conservatively treated cases in Copenhagen 73 per cent. died and 27 per cent. recovered. An English statistic of 384 conservatively treated cases, in all of which abscesses were present, showed a mortality of 67 per cent., a recovery of 33 per cent.

If abscess was not present, 69 per cent. recovered. Grosch (1882) found a mortality of 28 per cent. under antiseptic treatment.

Koenig states in a recent work, that it is an exception that a patient dies after resection of acute or chronic sepsis. In spite of the decreased mortality following resection, surgeons still differ in regard to the advisability of conservative or operative treatment. Two English surgeons of large experience, March and Wright represent well the different opinions. March is strictly conservative and considers excision uncalled for. Continued rest, he says, gives a mortality of only 5 per cent., and 70 per cent. recover with slight lameness and loss of motion. Even when suppuration has occurred he gives a mortality of only 6 and 8 per cent.

Dr. Wright, on the other hand, with an experience of more than one hundred cases of excision, of which only three died as a result of the operation, strongly advocates excision as soon as external abscesses occur, yes, even before the capsule has been perforated. He maintains that excision cuts short the disease, saves pain, lessens

the time of treatment and gives a better functional result. Osteomyelitis once established, nothing short of excision can, in his opinion, prevent the progress. Nature can, of course, get rid of the caries and necrosis, but the children who can survive the elimination are few, except among the well to do. The decreased mortality and the better functional result are the result of our increased knowledge of pathology and improved operative methods. Formerly we simply excised the head and perhaps neck and trochanter, but we left the tuberculous synovial membrane and discredited the operation because, as might be expected, suppuration continued or increased and our patients died of marasmus, amyloid degenerations, tuberculous meningitis or phthisis. Modern pathology has taught us that coxitis is primarily an osteitis, secondarily, a tuberculous synovitis and arthrititis, and that it is necessary not only to remove the bone affection, as we formerly did, but to remove the tuberculous synovial membrane just as well. If anything is left of that, relapse is sure to occur. The same is true about the tuberculous pyogenic membrane covering the abscess. If all diseased tissue of bone and synovial membrane is removed we may get healing of the wound by first intention even, just as we see it in operations on the knee-joint. I am even inclined to go a step farther than Wright, and advocate still earlier operation in order to remove the local focus before diffuse inflammation of bone and joint has occurred. I tried this recently in the case of a little girl, who had been sick six weeks and who had considerable infiltration around the neck. I made an anterior incision (Barker's), between Sartorius and tensor vagina femoris muscles and exposed the neck with ease, the extensor quadriceps femoris being pulled inwards. I found under this muscle a great mass of tuberculous material, which had not yet broken down into pus, and removed it, but I could not find the local focus, although, by flexing the hip-joint, I could examine the whole lower surface of the neck. I closed the wound with sutures and it healed by first intention. She did not improve, and three weeks after I resected the joint, found the sequestrum, three-fourths inch long, near trochanter, and a complete disorganized joint, diastasis of the epiphyseal cartilage, etc. The patient left the hospital recovered in three weeks. I show you the preparation here.

Mr. W. H. Battle reports a similar case in the London Clinical Society. He successfully removed a local focus, washed out the joint, and the child recovered in four weeks.

If the disease commences in the acetabulum (and according to Habernr this should occur in five out of eight cases), operation would be still more indicated, as the dangerous complication of intra-pelvic abscess is apt to follow. This com-

plication has formerly been considered an absolute indication for resection, but Bardenheuer, of Cologne, has several times resected acetabulum in such cases, by aid of his symphyseal incision (extra peritoneal explorations—Schnitt). But even if it is possible, yes, comparatively easy, to resect the acetabulum in this way, we are forced to leave behind the tuberculous synovial membrane and the secondarily affected head and neck of the femur, and the disease, I judge, would proceed in spite of this operation.

Still one question remains, whether the limb is better after the excision or after conservative treatment?

Holmes thinks that shortening is generally greater after excision and the limb less firm and less useful. Motion is more frequently present and more extensive, but the patients walk more insecurely and with more limp. Jacobson thinks the average results obtained by conservative treatment superior to those following excision, particularly in adults, where we often get flail-joints after excision.

Wright, with his large experience, thinks that excision gives better results and that much shortening depends upon using the limbs too early.

It is evident that the best result following excision cannot compare with the best result following conservative treatment: *restitutio ad integrum*. We must compare those conservatively treated cases, who have got well in spite of abscesses, caries and years of suffering, with those, in which, for the same reasons, excision was made. Few get well by conservative treatment, extending during years, without considerable flexion and adduction. To treat such a case demands such continual patience from the side of the parents, the patient and the surgeon that a good functional result is almost out of the questions unless the patient be treated in a hospital, where the surgeon has complete control over the patient and nurses. It might therefore more properly be asked, whether a flexed and adducted limb is more useful than a shortened limb after resection?

Judging from my own limited experience, I believe that excision gives a better functional result and a better looking leg than does conservative treatment in the majority of cases, particularly if you can sever the bone above trochanter minor. If you are forced to go below trochanter minor you are very apt to get a flail-joint. In early, or comparatively early operations, the disease will probably always be found confined to the head and neck.

I have during the last few years resected the hip-joint ten times, eight of which recovered with good and useful limbs, two died of other causes, independent of the operation.

The earlier the operation has been done, the better has the functional result been and the

quicker the recovery. The last two cases, the pathological specimens of whom I have shown here, left the hospital with healed wounds in three or four weeks, but have, of course, not yet been allowed to use their resected limbs. Most of the cases presented themselves in the third stage of coxitis with extensive carious destruction, large abscesses and broken down constitutions. Yet even these cases, who had been treated conservatively for a long time, were by prompt excision restored to health and comfort and provided with a firm and useful limb.

OSTEO MENTHESIS.

Read in the Section of Surgery and Anatomy at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY B. MERRILL RICKETTS, M.D.,
OF CINCINNATI, O.

I wish to call your attention to the subject of osteo menthesis, the subject of which I made brief mention at the last meeting of the New York State Medical Association, which convened in New York City.

Dealing with bone tissue has been one of the most interesting subjects to me, and I may say to surgeons in general.

The three principal points which I wish to bring out in this paper are as follows:

First: How and when may bones be restored?

Second: Should fragments of the bone be permanently removed except in case of amputation?

Third: Should not exploratory incisions be made in cases of fracture of bones where doubt exists as to their character?

I cannot do better, after making brief mention of these three interesting features, than to report the observations I have made in experimenting with the lower animals.

In the first case: How and when may bones be restored? I would say, in this class are included those cases in which the restoration of the bones, of the hands, feet, arms and legs have been removed by trauma or surgical interference without amputation.

Bone grafting, or osteo menthesis, is subject to as great a number of successes as skin grafting.

I am thoroughly satisfied, after having carried on my experiments, during the past year, that its confines are not narrow by any means.

It was Poncet, who restored the tibia within nine months, by grafting to the superior articular surface. The replanting of trephine buttons is now the established rule.

The dentists have accomplished a great deal in transplanting, replanting and implanting teeth.

The series of experiments that I have adopted to show what can be done in the way of substitution, that is, transplanting the bone of one animal to another, is not as yet complete. Suffice it

to say, that enough has been accomplished to satisfy me that sooner or later, the long bones and ribs of the lower animals will be successfully transplanted for the purpose of restoring osseous structures, destroyed by any cause whatever, except that of malignancy.

I am inclined to believe that the tails of such animals, as the dog, cat, opossum, etc., after being divested of the integument and soft tissue, may be transplanted with success, as the various joints will become ankylosed, and they may perhaps supply a long felt want.

It may be found that the ribs of the lower animals can be substituted for metatarsal and metacarpal bones.

In all cases as much of the periosteum should be preserved as possible, and the bones cut with a knife or chisel, or the finest saw that can be had, preference being given to the knife, as the ends of the bones are smoother, a condition more likely to be followed by good results than if severed with a saw. I have not yet been able to save a finger, in case of injury, where the bone was completely divided by a saw; I have, however, been successful in securing union in several instances where the bone was severed with sharp edged tools. In all cases of injury when the bone is divided by the saw there is more or less foreign matter, fine in character, carried into the wound, and its removal is attended by the greatest difficulty. Thus it is these two elements, a roughened bone surface and foreign matter, that make union difficult, and yet, with the larger bones, it is absolutely necessary to use the saw. This once done, the ends may be scraped and perfectly coapted, after which the periosteum overlying the two bones is brought together and stitched with fine catgut.

I will say in this connection that I do not favor the use of the forceps in amputating any member; the objection lying in the possibility of fracture. The saw should invariably be used; with the forceps the work is more rapid but less scientific, and there is no excuse for any man applying them.

Second: Should fragments of bone be permanently removed except in case of amputation?

Bone fragments, in either compound or compound comminuted fractures. Where a bone is crushed or broken into two or more pieces, the greatest care should be taken to replace the fragments, and to offer every opportunity for their union so that its strength and original shape may be preserved. That this may be made more certain, all clots and foreign matter should be cleared away and shreds of tissue removed from between the fragments, which should be immediately restored to their proper places.

In some cases, as in long bones, the fragments may be brought together with a silver wire, which may afterwards be removed.

In dealing with the fragments, cleanliness is,

above all things, first to be considered. Each fragment should be thoroughly cleansed with water at a temperature of 115° or 120° . Constant irrigation of the wound with water at this temperature is by far more preferable. If the fragments have been removed from the limb by injury or otherwise, they may likewise be restored. In compound fractures, where there are two or more fragments, it is best to allow them to remain and clean by irrigation and scraping, as the periosteum overlying these fragments will enable union to take place much sooner. If a portion of the shaft has been removed and cannot be found, I am inclined to think that small fragments, such as shavings and dust, would be the most desirable way of restoring the lost part. These bones may be from the individual himself, or from any of the lower animals. This was first suggested by McEwen, of Edinburg, and it was by this means that he restored one-third of the radius in a boy.

I am also inclined to believe that bone grafting can be more successfully accomplished in persons under 15 years of age than those older. This can be readily understood when we consider the activity of development of bone up to this age. The bone is not so brittle and the vascular supply is more perfect. It is at about this age in life that we cease to find the green stick fractures.

I am also inclined to the belief that bone would be more easily grafted near the epiphyseal line.

It is an established fact that bone cannot be grafted to any other tissue than that of bone, and that epithelial tissue cannot be grafted to any other than epithelial tissue; so that, if we can secure a sufficient amount of periosteum to overlie these fragments or grafts we will have union more certain and rapid.

In cases of compound fractures, especially where the bone has been crushed, we must first ascertain the condition of the blood vessels and nerves. These being intact we may rest assured that our patient loses no time in making the attempt of saving the fragments or restoring any portion of a bone that may have been removed.

Third: Should not exploratory incisions be made in cases of the fracture of bones where doubt exists as to their character?

Being conscious of the great difficulty that is almost invariably encountered in determining the exact condition and character of fractures, my attention has been especially called to an investigation in this line.

It is so often the case in fracture of the long bones, especially in fleshy persons, that we are utterly unable to determine what the state of affairs is. Until a comparatively recent date the injured extremity was placed in a support of

some kind, and the bone allowed to heal *ad libitum*. Now, this having been an established custom for so many centuries, it may seem rather out of place at this time to suggest a different procedure, with my limited experience, from a practical standpoint, but having recently carried my observations over a series of experiments, I feel somewhat at liberty to bring this matter before you.

It is with chagrin and humiliation, many times, that we look upon the result secured in putting these fractures in plaster, or in any dressing whatever, and allowing them to take their course. We have no definite means of determining whether the fracture is transverse or diagonal. Now, this being the case, why are we not justified in making exploratory incisions in cases of fracture, as well as in obstruction of the bowel?

If cleanliness is the greatest desideratum—which I have every reason to believe it is—it is through clean surgery that we secure such brilliant results as have been secured within the past, why need we fear any serious consequences in making a simple fracture a compound one?

True, the bone will never be as perfect as it originally was, but then there is the great satisfaction of knowing whether there are one, two or three fractures.

In all cases of fracture, especially compound, there are more or less clots and shreds of tissue, perhaps muscular, ligamentous or cellular tissue, involved in the fracture. An exploratory incision will enable these to be removed and the fragments of bone closely coapted and union made more rapid and certain.

Of course, this procedure would be confined almost entirely to the long bones; however, the same rule would hold good in the injury of the cranium.

In cases of a blow received upon the head, we are not able to determine whether or not there has been a fracture either of the outer or inner table. The infiltration is many times so extensive that it is impossible to arrive at any definite conclusion. Now, why should we refrain from making a simple incision through the scalp, at any point, when the risks are so slight and where the good to be derived is so great?

One of the greatest principles involved in surgery, as in medicine, is to determine the cause and the state of affairs.

The sense of touch is of itself one of the greatest means of enabling us to arrive at definite conclusions.

However, the eye is equally important in many things; although it may not be possible to get a view of these fragments, it is possible for us to determine definitely what the condition is, simply by the sense of touch.

Many times the incision may not be any larger than to admit the index finger, but the finger once introduced, the state of affairs may at once be determined and thus save us from malpractice suits and the humiliation that we sometimes experience in treating fractures.

The incision once made, the question would then arise as to how the fragments of the bone may be best secured, that they may be replaced to their normal position and allowed to remain so until Nature comes to our rescue. I would say, in this connection, that I have found nothing to equal the silver wire, secured with an Aveling coil and mounted with a perforated shot. The wire may be passed around the fragments by means of a Collins' needle. The wire is made taut by an Aveling coil mounted by a shot. This may be allowed to remain indefinitely, as it causes no irritation. It may be removed at the end of four, six or eight weeks, in which case it is best to have the coil to stand at a right angle to the bone or the ends of the wire may be secured, the coil placed parallel with the bone, the periosteum be made to overlie it and allowed to remain. In this case, the bony structure is thrown out and soon encompasses the wire and its attachments. As many of these may be used as may be necessary. So far I have not seen any bad results. With one or two of the dogs I found that the integuments healed and that they caused no serious trouble.

The fragments once secured by this means, the wound should be closed and the drainage tube, which should be rubber, inserted; as we are more likely to need drainage in the reparation of the bone than any other tissue. As to the after dressing, I have found nothing better than the application of simple water dressings. These enable the wound to be kept soft and the discharge to escape freely. Towels saturated in boiled filtrated water, can be applied every hour or so as the occasion may require. It may, or may not, be necessary to place the injured extremity in plaster.

Of all the dressings, I think the plaster is the most desirable. It has been my desire in bringing this paper before you, to excite an interest in this very important matter; knowing that it will require a great deal of time, experimentation and observation to enable us to arrive at definite conclusions, in this as in all other matters, I am desirous of having your coöperation and assistance in bringing this subject before this Association at its next meeting, wherever it may be.

A JAPANESE MEDICAL NOBLEMAN.—The Emperor of Japan has named Dr. Hide Miyake, professor in the Medical Faculty of the Imperial University of Tokio, a member of the House of Peers.

AN ABDOMINAL WICK.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 1891.

BY ROBT. T. MORRIS, M.D.,
OF NEW YORK.

In my first sixty-three laparotomy cases, dependence had been placed upon a drainage tube that was so efficient, so ready at hand, and so simple in its workings that I thought it good enough to be patented. That drainage tube was the patient's intestine, running through the middle of the great lymph bag of the abdomen, and ready to abstract from the sac any collection of fluid that was enticing to microbes, and to set it out of doors where their fatal breath would be exhaled into valueless space as they fought for possession of the sports.

Deliquescent salts passed through the alimentary canal or injected into my drainage tube by way of the anus had cleared the great lymph sac by osmosis so regularly and with such ease that any other sort of tube seemed to be a superfluity.

But one day this fine drainage tube failed. The case may be spoken of unpoetically as "number sixty-four," in order to avoid the identity that goes with initials. There had been a moderate degree of oozing from adhesions after the removal of her large ovarian cyst, but this was not disturbing to my assistants at the hospital, who had often managed similar cases without a ruffle of anxiety as to the outcome. This patient's bowels, however, failed to respond to the seidlitz powder on the following day. Then a large dose of Rochelle salts was given without effect. The patient was rapidly developing a septic peritonitis, and continued attempts at getting an evacuation from the bowels by means of Rochelle salts by mouth and by rectum were failures. Finally I reopened the abdominal cavity and out ran a thin wicked stinking fluid that had caused all of the mischief, but it was too late and the patient gradually failed and died. Her family and her physician had put confidence in me and that was what I had done for them. An artificial drainage tube introduced at the time of the operation or at the beginning of the peritonitis would probably have saved the patient's life, and I should have been spared remorse; but if one could have all experience at once it would not be necessary to go to the bottom of such a dark well for truth. I could not believe in time that the patient's bowels were not going to act as other bowels under similar circumstances.

My reasons for not using artificial drainage tubes after abdominal operations had been good ones. I had known of several fæcal fistulæ that had followed the use of hard tubes, and secondary infection can easily take place through the stright and narrow way that leads to destruction. Soft tubes collapse. Gauze used for abdominal

drainage may become so firmly adherent to the intestines that its removal means peril for the patient. Then again I know that the introduction of artificial drainage tubes mean a good deal of extra trouble for the surgeon. Of course, no one cares how much extra labor and trouble he is put to if he can thereby save life and prevent suffering, but it seemed unnecessary, judging from my facts in experience up to the time of losing the patient just referred to. Since that time I have occasionally thought it prudent to use artificial drainage apparatus, and to avoid the dangers of hard and soft tubes, and of unprotected gauze. Wicks of the form here presented were used. The simplest wick consists of a little roll of absorbent bichloride gauze, around which is wrapped a couple of thicknesses of Lister's protective oiled silk. The gauze protrudes a trifle from each end of the cylinder, and a few little holes snipped through the protective allow serum to reach the gauze elsewhere. In certain cases where injections through a tube are desirable the soft rubber tube can be surrounded with this wick. When a large gauze packing for the pelvis is needed, an apron of the silk can expand out over the gauze and protect against intestinal adhesions. The wick acts by capillary attraction; the silk wrap will not irritate the peritoneum and the whole thing is so soft that it adapts itself to curves readily, and I doubt if it will cause fecal fistulæ. The end of a wick which

if each one lead up into a bunch of absorbent cotton or gauze. A little wick as big as a lead pencil will take pints of fluid out of the abdominal cavity and transfer it to the absorbent medium outside. When the wick is at work it is important for the patient to remain upon her back, for if intestines are not inflated with gas the fluid rises naturally to the anterior abdominal wall, instead of settling, as many surgeons suppose, in the region of Douglas' pouch. If the patient turns upon her side the fluid rising to the highest point will be out of reach of the wick. The relative positions of peritoneal exudation or of blood serum and intestines will vary with the amount of gas in the intestines, but ordinarily immediately after work upon abdominal contents it may be observed that all free fluid is rising toward the anterior abdominal wall, and that is why the little holes are snipped through the silk of the wick at various points.

Apron and wick.

My drainage tube No. 1, is still the intestine.

My drainage tube No. 2, is the wick, and this row of wicks at work in the pan of water is speaking more forcibly than I can to you who are observers.

133 W. 34th St.

projects at the external opening of the wound should be covered with enough absorbent cotton or gauze to hold all fluid that is coming from below. In the pan which I now fill with water a row of these wicks is introduced. And as you see, they empty the pan in a few moments by siphon action. They would empty it almost as quickly

PROF. REURERS, of Berlin, has used the cantharadinate of potassium (Liebreich's remedy) in a severe case of diphtheria, with prompt and favorable results. Reurers was led to try the remedy because of its effects upon swollen and infiltrated tissues, believing that it might have a specific action upon the diphtheritic membrane. The favorable results in the single case in which it was tried will lead to further observations.

AN open competitive examination of candidates for junior assistant physician in any of the State hospitals and asylums, will be held at the office of the Civil Service Commission, Albany, N. Y., Thursday, August 20, 1891, commencing at 10 o'clock A.M. A candidate for the position must be a citizen of the State of New York, at least 21 years of age, and have had at least one year's experience in a hospital, or three year's experience in the general practice of medicine. For application blank, address the Secretary of the New York Civil Service Commission, Albany, N. Y.

JOHN B. RILEY, Chief Examiner.

FURTHER PROGRESS IN MEDICAL EDUCATION IN NEW YORK.—The Medical Department of the University of the city of New York makes certain special announcements this year which should have a very general interest, indicating as they do a decided advance in educational methods. First: The Faculty have placed the college upon a true university basis; that is, the pecuniary interests of the college have been put entirely in the hands of a body separate from the Faculty, while the latter receive fixed salaries, and are free to give their time and energy to advancing the standard of the curriculum unincumbered by financial care. This step makes the Faculty quite independent of the number of students who may attend the college classes.

A second change consists in making the three years' course obligatory; and a third, perhaps the most important of all, consists in the introduction of the recitation system in place of the didactic lecture during the first and part of the second year.—*Medical Record*.

A DOMESTIC STERILIZER.—There are few houses in which a ready sterilizer is not at hand, namely the kitchen oven. The heat which can be generated in this culinary appliance would be more than sufficient to destroy those forms of germ life which are inimical to wound treatment. With a clean receptacle at hand, into which towels and other appliances required for the purposes of an operation could be placed, the kitchen oven could be relied on to effect the necessary sterilization of these with convenience and dispatch. Thus as an improvised "sterilizer" we can easily conceive of the occasions when a surgeon would be glad of the assistance of the kitchen oven.—*Medical Press and Circular*.

PHYSICO-CHEMICAL RESEARCHES ON THE ALIMENTARY FEATURES OF MILK.—In an interesting communication to the *Journal de Médecine de Paris*, Jolly calls attention to the necessity of a due proportion of phosphate of lime in milk, in order that it shall be capable of maintaining nutrition. Milk, to properly nourish an infant, and supply a sufficient quantity of phosphate of lime for the purposes of ossification, should contain at least 1.25 G. of phosphate of lime per litre. The needs of the infant economy are abundantly provided for by normal human milk, which contains about 450 G. of mineral constituents per litre, of which about one-half, or 225 G., is phosphate of lime. He cites the following cases illustrating the foregoing:

First Observation.—A nurse, aged 23 years, had been delivered about three months before. She had nursed a child twenty days. At the beginning the child had gained between 13 and 19 G. Towards the twentieth day it was observed that it had lost 26 G. in two days, and 300 G. on the weight which it had at birth. The nurse was changed and the child improved. An analysis of the nurse's milk showed it to contain the fat, casein and sugar in nearly normal proportions, while the mineral salts were only 1.50 per 100, or about 0.75 G. of phosphate of lime per litre.

Second Observation.—The nurse, a Breton of 24 years,

of average height, well proportioned, appeared to enjoy perfect health. Her milk per 1,000 G. contained: casein 35.00; fat 43.30; milk sugar 51.80; mineral constituents 1.60. The child increased only about 7 G. per day, and at the end of three weeks, for several days, it lost 15 G. per day. The nurse was submitted to a phosphatic treatment. At the end of four or five days the child was seen to pick up, and after the eighth day gained regularly 20 G. per day. It need only be stated that the phosphate administered was not the phosphate of lime.

Third Observation.—The most feebly mineralized human milk which Jolly has met with, merits attention. Its composition per 1,000 was as follows: Casein 8; fat 74; milk sugar 54; mineral constituents 0.40. This milk, extremely rich in fat, was extraordinarily poor in casein and mineral salts. The nurse was an obese woman of 32 years. She had a freshness of complexion, and amplitude of form, which is generally considered as representing the very type of vigor and health. Like most persons who have a tendency to fatty degeneration, this woman used mostly farinaceous food for alimentation, to the exclusion of meat. It goes without saying that the child which she nursed sank steadily. Attention is called to this milk for the following reason: The physician is frequently called to assist families in the choice of a wet nurse, and he is generally contented with a physical examination of the milk. Now, in the case in question, the milk had a creamy and rich appearance which was certainly deceptive as to its nutritive value.

The phosphatic composition of the milk of the cow similarly undergoes considerable variations, dependent upon the quality of the food and the abundance of the lacteal secretion. While it is not uncommon to find milk containing 4 or 5 G. of phosphates, Jolly has met with a natural milk, not adulterated, which, while it contained the organic constituents in nearly normal proportions, had only 1.05 G. of the different phosphates per litre; that is to say, a quantity absolutely insufficient to serve usefully as a food for an infant.

The preceding examples are intended to show that the mineral richness of woman's milk, and cow's milk, are not always so great as some analyses seem to indicate; that the phosphatic richness of a milk has not only a considerable importance with reference to ossification in the child, but also as to its general growth.

In consequence, the determination of the phosphoric acid in milk must be made, before its nutritive value can be known.—*Journal de Médecine de Paris*.

A NEW private polyclinical institute of some importance, and on a large scale, has just been opened in Berlin. It is to go by the name of the "Johanneum." The instruction is to combine hospital practice with clinical instruction and theoretical research. It contains eighty beds, is furnished with laboratories, microscope rooms, etc., an electro-mechanical institute, and a lecture theatre, in which courses are to be given by Professor Eulen-berg on diseases of the nervous system; by Professor Zülzer on diseases of the kidneys and bladder; and by Dr. Scheimann on diseases of the nose and throat.

CALMATIVE FOR HYSTERIA.—

R. Chloral hydrat.

Sodii bromid., āā ʒj.

Ext. Hyoscyami, three-fifths gr.

Ext. cannabis indicæ, three-fifths gr.

Mucil. acaciæ, ʒij.

M. S. Dose, 2 to 4 drachms, every half to one hour, in a cup of orange-flower water. Specially useful for hysterical patients who complain of night terrors and insomnia. —Grassett, *La Méd. Moderne; Times and Register*.

Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to
JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,
CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

BY-LAW IV.—THE PUBLICATION OF PAPERS AND
REPORTS.

No report or other paper shall be entitled to publication in the volume for the year in which it shall be presented to the Association, unless it be placed in the hands of the Board of Trustees on or before the first day of July. It must also be so prepared as to require no material alteration or addition at the hands of its author. Authors of papers are required to return their proofs within two weeks after their reception; otherwise they will be passed over and omitted from the volume.

Every paper received by this Association and ordered to be published, and all plates or other means of illustration, shall be considered the exclusive property of the Association, and shall be published and sold for the exclusive benefit of the Association.

The Board of Trustees shall have full discretionary power to omit from the published *Transactions*, in part or in whole, any paper that may be referred to it by the Association, or either of the Sections, unless specially instructed to the contrary by vote of the Association.

SATURDAY, JULY 25, 1891.

ETIOLOGY OF TETANUS.

A recent communication by SANCHEZ-TOLEDO to the *Société de Biologie* of Paris, recalls this subject.

The first bacteriological work upon the etiology of tetanus was that of NICOLAÏER in 1884, who then described his earth bacillus, which has since come to be recognized very generally as the tetanus bacillus. NICOLAÏER found that tetanic symptoms followed the introduction under the skin of mice, rabbits and guinea pigs, of soil from streets and fields. In the pus which formed at the site of the inoculation the tetanus bacillus was found together with other microorganisms. NICOLAÏER did not obtain a pure culture, but KITASATO and others afterwards succeeded in producing pure cultures of this bacillus. The difficulties met by the earlier workers with this microorganism seem to have been due to their failure to recognize the anærobic character of the organism. It is now clearly established that the bacillus ceases to be virulent if exposed to oxygen.

In attempts to produce cultures of NICOLAÏER'S bacillus, other anærobic bacilli are usually found contaminating the cultures. Some of these ba-

cilli, like NICOLAÏER'S, are spore producing, but the spores of the tetanus bacillus appear earlier than those of any of the others. Now, since spores can withstand a temperature greater than that of the fully developed bacillus, the way was open to purify the culture by subjecting it to such a degree of heat as would destroy bacilli but not destroy the spores, at a time when the spores of the tetanus bacilli had made their appearance, and before the spores of the other organisms had developed. This method was elaborated by KITASATO, and pure cultures obtained.

It has been observed that the tetanus bacillus is to be found only in the immediate vicinity of the point of inoculation, and never in the blood or other tissues of the animal. This would seem to indicate that the effects were due to chemical products formed at the seat of inoculation.

Several years ago BRIEGER obtained from an impure culture of the tetanus bacillus a ptomaine which he called tetanine, and which, when injected into animals, particularly mice, produced tonic and clonic spasms of a tetanic type. Later, he extracted from the amputated arm of a man suffering with tetanus a ptomaine, apparently identical with his tetanine. More recently BRIEGER and FRÆNKEL have separated a toxalbumin from pure cultures of the tetanus bacillus, to which they have given the name tetano-toxine.

VAILLARD and VINCENT, in January, 1891, announced that pure, sporulated cultures of the tetanus bacillus, freed from their toxins, and injected in considerable quantities under the skin of susceptible animals, did not develop at the point of inoculation, nor produce tetanus. It seemed from their observations, that until the organism had grown for some time in an artificial culture medium, it was not capable of producing the disease, which was accounted for by finding that no poison was developed until some time after the organism had begun to grow, the production of this poison appearing to go on simultaneously with the formation of a peptonizing enzyme. A month ago, SANCHEZ-TOLEDO, having repeated the experiments of VAILLARD and VINCENT, reported his results to the *Société de Biologie*.

SANCHEZ-TOLEDO subjected pure cultures of the NICOLAÏER bacillus, in bouillon and gelatine, to temperatures of 70° C., 80° C., and even 90° C., for an hour, on a water-bath. At the same time,

he subjected to the same conditions control tubes containing filtrations from pure cultures of the bacillus, *i. e.*, solutions of the toxins, freed from the bacilli. Inoculations of considerable quantities of the contents of the control tubes produced no effect upon animals, proving the destruction of the toxins. Nevertheless, the pure cultures remained active, as the inoculation of one-half c.c. killed guinea pigs in twenty-four hours, and one-tenth c.c. killed mice in forty-eight to sixty hours, with tetanic symptoms.

He also secured cultures free from toxins by washing thoroughly with sterilized water through a Chamberland filter, after the manner adopted by VAILLARD and VINCENT. Ten c.c. of bouillon or agar culture was in this way washed with six to ten litres of water, and the remaining culture diluted with six c.c. of pure water. One-twentieth c.c. of this mixture inserted under the skin of mice caused death with tetanic symptoms in from forty-eight to eighty hours. One-fourth c.c. killed a guinea pig in less than eighteen hours with tetanic symptoms. In all the experiments the tetanus bacillus was found at the point of inoculation as was proven by microscopic examination, culture and inoculation. Moreover, it was found there in pure culture, without any other microorganisms, showing that tetanus could be produced by this organism without the intervention of any other form of bacterial life.

The disagreement, real or apparent, between the observations of SANCHEZ-TOLEDO and VAILLARD and VINCENT, awaits explanation.

We shall look forward with interest to the establishment of one or the other of these views, or to filling of the gaps by which they may be reconciled.

It can hardly be doubted, however, that Nicolaier's bacillus is a cause of tetanus, but the whole history of the germ shows that the conditions of its growth are as yet unknown, and probably are quite complex. It is a knowledge of these conditions which will give the predisposing causes of tetanus, and explain why, notwithstanding the wide distribution of this germ, that tetanus is so uncommon, and why tetanus sometimes makes its appearance in epidemic form, as it did in the United States in 1882, at which time the over-zealous newspaper reporter threw the blame on the toy-pistol.

TUBERCULAR INFECTION BY MILK.

DR. OLLIVIER, one of the physicians of the Hôpital des Enfants Malades, at Paris, has recently read a paper before the Academy of Medicine, on the dangers of milk-tuberculosis. He states that he was called upon to go to Chartres to consult concerning a case of tubercular meningitis. The patient was a young lady, aged 20, whose family history and personal antecedents were excellent, and whose hygienic surroundings were believed to be all that could be desired. But she had been placed at a small boarding school at Chartres, which, upon investigations proved to have been unusually afflicted by tubercular disease. During the preceding four years six out of thirteen scholars had successively or simultaneously become tuberculous; two of the cases having been *tabes mesenterica*. This was manifestly the place where the patient of DR. OLLIVIER had contracted her disease, which not long afterward resulted in death. An inquiry was instituted to ascertain the cause of this unfortunate series of cases, and it was found that the milk supply of the school had for some years been contributed to by a cow having a tuberculous udder; this cow had been brought every day to the convent to be milked and her milk had been consumed unboiled by the inmates. This non-boiling of the infected milk was held by DR. OLLIVIER to be the sufficient explanation of the series of cases at the school, and was made the basis of an argument in favor of the invariable boiling of milk, whose source has not been sanitarily proved to be free from tubercular contamination. In the discussion following the paper, DR. NOCARD stated that he had formerly expressed the opinion that all milk, from any unknown or suspected source, should be boiled before being used as food. But he now went further and advanced the necessity of a rule that no milk, whatever may be its source, should be consumed in the raw state. He related a case that had only a short time before come under his observation. He was called upon to examine the lymphatic glands of a calf, apparently in healthy condition, which, much to the surprise of its owner, had died after only a few days' illness. These glands were found to be full of tubercular bacilli. Not long after this discovery, the mother of the calf—a fine appearing animal, and the winner of several prizes at

shows—also died, and the udder, lungs and glands were examined and found to be tuberculous. And this is not by any means the first instance that handsome, prize-winning cows have been the unsuspected subjects of that disease. There is room here for much investigation as to the point at which the milk produced by these animals becomes dangerous by the conveyance of bacilli into the human alimentary canal, and what, on the other hand, are the elements in the human economy which grant immunity to such large proportions of exposed persons. Another line of investigation is also promised, in regard to qualities of condensed milk, which can hardly fail of interesting the profession, especially in those cases where the condensing factories are known to receive milk from dairies containing a number of tuberculous kine. This research is about to be undertaken by one or more of our own State Boards of Health.

LEGISLATION AGAINST THE IMPORTATION OF COMMUNICABLE DISEASES.

On April 1, a new Federal immigration law went into operation, whose ostensible purport is the shutting out of imported infectious disease, liable to be sent hither, from European ports, especially. The preliminary trials of the working of the new law have already been set in motion at the port of New York. Already there have been some cases of pulmonary tuberculosis and alopecia debarred from entry. Some little time will necessarily be spent in legal contest and opposition by the friends of indiscriminate immigration before the holding or effective properties of the law will be known. It is believed, however, that the act is sufficiently strong to prohibit some of the undesirable elements which under the old law were free to enter. One of the peculiar features of the new act is that it does not recognize an immigrant as landed until he has been passed by the Landing Bureau, of the Department of the Treasury. The steamship companies are thus made the custodians of all persons who are denied entry for physical reasons; and they become responsible for the care and maintenance of those persons so long as the importing vessel remains in port, and on her departure she must take away the rejected material. As a natural consequence some of the companies have

already advanced their rates for steerage traffic, which, of itself, will tend to purify the stream of immigration. Another salutary influence of the new law is that the steamship companies will become more cautious about the class of people they permit to come to this country on their vessels, and it may lead up to a preliminary physical examination by competent medical inspectors. When this good end shall have been accomplished, a very weak spot in our international relations will have been touched—a spot that has been repeatedly pointed out in our medical and sanitary contemporaries.

In British America, medical attention has been turned to the frequent importation of leprosy cases, from Asia. Medical men have recently investigated such cases at Victoria, British Columbia, and have recommended that their increasingly rapid importation should be checked by legislation. It is stated that there has been a considerable spread of the disease during the last year in nearly all the Pacific cities of the Dominion, and has reached a point where its further advance must affect disastrously the prosperity of British settlements there.

IMMIGRATION AND PUBLIC HEALTH.

While our sanitarians and public health authorities are deeply concerned with the possible importation of some cholera infected rags or clothing containing the germs of small pox, it may be well to call their attention to another and very serious disorder affecting the public health.

The treasury bureau of statistics has recently made a report on immigration, from which we excerpt the following figures: The number of immigrants from 1789 to 1820 is estimated at 225,000. From that time the number for each decade is as follows: 1820 to 1830, 143,400; 1830 to 1840, 599,100; 1840 to 1850, 1,713,200; 1850 to 1860, 2,598,200; 1860 to 1870, 2,466,700; 1870 to 1880, 2,944,600; 1880 to 1890, 5,176,200.

It scarcely needs comment to show the enormous influence that such a vast mass of immigration has upon the health, welfare and prosperity of this country. A number equal to one-twelfth of the entire population of the United States, and equal to the population of the great State of Pennsylvania, added to this country in a single decade! It is a notorious fact that the

quality of this vast stream of humanity has diminished with each decade, and in just about geometrical ratio with its increase in numbers. What a change from the days when men set out across the seas to escape persecution or to secure wider civil and religious liberty, to the time of "assisted" immigration, when men leave their country not for their own good, but the good of their neighbors. Can we estimate the amount of crime, ignorance and insanity that will be inflicted upon this country in the defective descendants of these wretched beings?

Every town of any considerable size in Europe has at least one agent of a steamship company who are industriously circulating false stories regarding the rates of wages in this country and the ease with which employment is obtained. These agencies, together with the influence of relatives already living in this country, and the "assistance" freely given by local officers to undesirable persons, has pushed the annual increment to enormous proportions. The absorption of such a mass of reputable and fairly well-to-do persons would severely tax the resources of even this great country, but what shall be done with this vast mass, when the majority are found to be mentally, morally and physically far below the average of mankind?

In our opinion, it is none too soon to grapple with this great problem. Already the public service of our large centers of population are beginning to struggle under the vast mass of criminality, pauperism and insanity poured into this country from the continent of Europe.

Recently the proposition to add a medical officer to the cabinet has been freely discussed, and much has been said pro and con. To our mind, the urgent need of such an officer is shown if he is to deal with no other subject than that of immigration, a question fraught with mighty consequences to this nation, and beside which questions of war, famine and trade sink into comparative insignificance.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

This body is constituted of the several specialty organizations of this country; and convenes once in three years in Washington. The next meeting will be held in that city September 22, 23, and 24.

These societies embrace in their membership many of the leading and most enthusiastic investigators and observers in our profession. In addition to the triennial Congress each of these societies hold an annual meeting, where papers are read, notes compared and a résumé of the year's progress is compiled for publication in handsome volumes. Unfortunately these volumes of transactions are issued in quite small editions and in distribution rarely reach beyond the limited membership of the several societies.

We are glad to note that very many of the members of these organizations are also active members of the American Medical Association. We rejoice at their affiliation, for they are the men who are best known to the great body of general practitioners; they are the men who realize most fully the value of society work, of communion one with another. This gathering of men engaged in diverse pursuits, but still members of our profession, is beneficial to all. It broadens the mind of every man who attends the meeting, and as their work is reflected through the journals, does good to every practitioner.

It is frequently charged that specialists are narrow in their views, that everything pertaining to their chosen department is magnified at the expense of the whole. The men who attend general gatherings of members of the medical profession are not the ones afflicted with obliquity of vision. They know that personal contact and observation will often change an opinion.

The social enjoyments of these occasions go far in lightening the drudgery of practice. Each meeting is remembered as one of the green spots in professional life. Attendance pays in length of days, lessening of wrinkles and improvement of digestion.

THE ARIZONA CLIMATE IN WINTER FOR INVALIDS.

DR. G. S. LIGGETT, of Oswego, Kan., writes to the *New York Medical Journal* concerning the climatic conditions of a part of Arizona which was visited by him during the winter of 1890-91. He spent most of his time at a point about forty miles distant from Tucson, in the foot-hills of the Catalina Mountains, and he reports that he found there conditions and qualities that commend themselves to consumptives and other invalids. He says: "For an outdoor winter climate

I do not think that the region can be beaten, and high up in the mountains there are magnificent places for summer resorts, and the time ought not to be far distant when our physicians will send their patients westward rather than 'across the pond' for a change of climate and scenery." He took thermometric observations from October to and nearly through the month of January, 1891, and he prints the record in full for the benefit of physicians. There was only one cold snap, occurring in the middle of January and lasting only three days. The wind from the snow clad mountains was at times quite cool. The hardest rains were in the night-time, and there was one little flurry of snow. They had three rain storms during the three months, but it was only during the time the rain was falling that the invalids needed to remain indoors. Thousands of song-birds have their winter quarters there. The party was housed at a ranch forty miles, by stage-route, from the railroad and up among the live-oaks. Their supplies included the choicest of mutton and beef, and abundance of fresh vegetables all winter, seasoned with an appetite that could enjoy everything that came before it. They aimed to lead an exclusively out-of-door life, walking, riding and hunting. The roads were excellent, and game—as quail, antelope, deer, coyote and wild hogs—was plentiful. There was no dampness nor sign of mold anywhere. The soil was so dry that the occurrence of rain was a decided advantage to the roads. The hours of sunshine were many, but no proportionate record of their number has yet been taken. The scenery is variously attractive, with views of *mesa*, foothills, mountains, valleys and cañons, and there was no lack of interesting objects to visit and engage the mind and attention of an invalid who was desirous of passing his time in the open air.

THE ISLAND OF ST. KILDA.—A cablegram from London, July 21, 1891, to the daily papers, calls attention to a mysterious malady which is affecting new-born infants on the little island. It says:

"The symptoms of the disease appear about the eighth day from birth. The hands close and remain rigid; a kind of lockjaw follows; the muscles of the face contract; the mouth is closed, and in a few hours more death ensues. From the appearance of the first symptoms until dissolution, twenty-four hours elapse. One family have lost twelve children in this way, and all the families on the island have lost from two to eight children by the singular disease. The first-born of each family generally lives. The doctors are inclined to attribute the malady

partly to the habit among the islanders of intermarrying among blood relatives, and partly to the fact that the diet of the people is limited almost entirely to oily food, such as birds and fish. There are only about 100 people on the island, and they are so closely related as to really form hardly more than one large family."

This condition of affairs has long been known on St. Kilda. The influence of the intermarrying, however, is negated by the fact that children of the natives of St. Kilda born elsewhere than on the island, do not become affected with trismus neonatorum.

According to Hollaud, trismus neonatorum prevails so extensively on the island of Heimæy, one of the Icelandic group, that the population is maintained almost entirely by immigration.

On this island, as at St. Kilda, the diet is almost exclusively one of fish and sea birds, and the custom prevails of feeding the infants this strong and oily food soon after birth. When, in addition to this fact, the remarkable uncleanness of the natives is recalled, we may certainly be justified in supposing the cause of the tetanus to be in a poison contained in the food.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

An official record of the four executions by electricity at Sing Sing prison on July 7th, has now been published, and it fully confirms the correctness of the first newspaper reports as to the admirable manner in which they are conducted and the instantaneousness and painlessness with which death was in each instance produced. In accordance with the provisions of the new statute the warden of Sing Sing has sent to the county clerk formal certificates of the four executions accompanied by a report of the observations of Dr. Carlos F. MacDonald, President of the State Commission on Lunacy, and Dr. Samuel B. Ward, of Albany, who served as the official physicians at the executions.

In their report the physicians state that all of the condemned walked into the execution-room unaided, with firmness, and without assistance, quietly seated themselves in the electric chair and submitted without resistance to the adjustment of the retaining straps and electrodes; that in each instance unconsciousness was produced instantaneously by the closure of the circuit, was complete, and persisted without interruption until the heart's action had entirely ceased and death had certainly occurred; and, thirdly, that an autopsy was made in each instance as soon as practicable by Dr. Ira T. Van Gieson, of New York, under their supervision, with the result of revealing the same gross changes in the blood and tissues previously observed in cases of death by the strong electric currents. They then stated that specimens, especially of the blood and of the nervous system, were procured for microscopic examination, the results of which would be presented as soon as the examinations were completed.

In conclusion they congratulate the warden on the completeness in all their details of all the preliminary arrangements, on the uniform good order and decorum, which prevailed during the trying ordeal, and on the resulting demonstration of the rapidity and painlessness of this method of inflicting the death penalty. "The experience of to-day," they say, "has proved to our satisfaction that this method is superior to any other yet devised."

The grand jury has made an appeal for a change in the condition of the inmates of the city asylum for insane females on Blackwell's Island, which certainly ought to be heeded by the authorities, and it is to be hoped that the Board of Estimate and Apportionment will now provide for the urgent necessities of the case. For a long time past this institution has been greatly overcrowded, so that 1,700 women have been huddled together in buildings originally intended for 1,200 at the outside. While there is urgent need for repairs and improvements in the buildings on Blackwell's Island, it would seem far wiser, rather than to increase the capacity of these buildings, to make suitable provisions for the overflow at the city's farm for the insane which was established a few years ago at Central Islip, on Long Island, a very salubrious rural district situated midway between the ocean and Long Island Sound, and which has thus far proved a very successful experiment.

Dr. Wm. J. Morton, the well-known specialist in diseases of the nervous system, has expressed the hope that the city of New York may at some future time have all its insane cared for in some such manner as at the colony for the insane at Gheel, in Belgium. "There," he recently said, "the picture is unlike anything to be seen in America or elsewhere in Europe, and therefore valuable for its contrasts and its suggestions. It is unusual to see the insane living their lives in natural surroundings. Gheel teaches us the possibilities that exist in the treatment of the insane. It shows us that they will work cheerfully if well managed, and that they may be treated, under proper precautions, with great liberty, and not abuse it. It teaches us, moreover, how woefully wide our advanced civilization is from the mark it might attain to in the treatment of insanity.

"The new and stringent immigration laws, providing for the examination and return on the vessels which brought them of all pauper and diseased emigrants landing in this country, have not gone into effect any too soon. For years it has been notorious that such dependent persons have been shipped to the United States by municipal authorities and so called benevolent societies in the old world; and during the past seven years the New York State Board of Charities has returned to their homes in Europe no less than 1,374 permanently disabled and helpless alien paupers who had been sent here to become a burden upon the tax-payers of this State. In the reports of the Board, these 1,374 persons are divided into the following classes: Lunatics, imbeciles, feeble-minded, vagrant and disabled, decrepit, cripples, blind, epileptic, paralytic, deaf-mutes, and otherwise infirm. The cost of removing these persons from this State to their homes in Europe ranged from \$2,451 to \$6,708 per

annum, but it is probable that in no other way could the Board have saved more for the people of New York. Said the Board in its report for 1890:

"Estimating the duration of life of this class of dependents, had they been allowed to remain in this country, at the minimum average of fifteen years, an ultimate saving of \$2,427,360, independent of the expense of housing them and providing salaried officers for their care-taking, is definitely proved, and an illegitimate burden on our people is thrown back where it originated, and where it justly and naturally belongs."

According to the bulletin of the New York State Board of Health, the mortality in this State in the month of April was the largest ever recorded. This increase was due to the epidemic of influenza, the deaths from which numbered nearly 5,000. The total number of deaths was 13,981, or 1,500 greater than in January, 1890, when the largest number of deaths ever reported up to that time for one month was recorded. This represents an annual death rate of 30 per 1,000 of the population.

One night, not long since, a man was brought to Bellevue Hospital with a slight wound over one eye, and in a state of unconsciousness, which was believed to be due to intoxication. The next day, however, he died. It was learned that he had been stabbed in the eye with an umbrella, and the autopsy showed that the ferrule had penetrated nearly three inches into the brain, producing fatal hæmorrhage.

P. B. P.

New Surgical and Pathological Society.

Getting the Hospital and Ambulance Service in Readiness for the Meeting of the Grand Army of the Republic.

To the Editor:—The profession in Detroit are at present interested in making arrangements for the medical and surgical care of the veteran soldiers who meet in this city early in August. A committee composed of representative practitioners, under the chairmanship of Dr. E. L. Shurly, have the work in charge. They have divided the city into ambulance districts, established medical relief stations at intervals along the line of march, and gotten the hospitals into special condition for the reception of the old soldiers who may happen to be taken sick or be injured while here. The demands of irritable bladders and prostates are to be particularly looked after by the erection of a large number of latrines where they will be most accessible. It is said that in some cities which have been crowded during the meeting of the G. A. R., much suffering has resulted from the neglect to erect proper conveniences. The medical men of Detroit will spare no pains to make the reunion of the soldiers successful and pleasant.

A new medical society has been organized here. It is known as the Michigan Surgical and Pathological Society. It adopts the Code of the American Medical Association, and has for its object the encouragement of surgical and pathological research, and the maintenance of a museum of gross pathology—a department of knowledge which many doctors in Detroit and Michigan think has been neglected, and has suffered by the greater en-

couragement which has been given to microscopical research.

Dr. Hal C. Wyman is the President, Dr. Lewis E. Maire, Vice-President, Dr. W. R. Scurr, Secretary, Dr. Wm. J. Hamline, Treasurer, and Drs. F. S. Hough and R. S. Linn, Curators. The presentation to the Society of a pathological specimen is a requisite for membership. A cash prize will be given once a year for the best original paper on some surgical or pathological topic.

Detroit, July 28, 1891.

X.

NECROLOGY.

Frank Hamilton Potter, M.D.

Dr. Frank Hamilton Potter, of No. 273 Franklin street, Buffalo, died July 16, after an illness of ten days' duration.

He was the only son of Dr. William Warren Potter, of 284 Franklin street, and was born in Cowlesville, Wyoming county, January 8, 1860, being in his thirty-second year at the time of his death. In 1882, when he was twenty-two years of age, he was graduated from the Buffalo Medical College. Prior to this time he had served as resident physician in the Rochester City Hospital for two years. In 1883, at the organization of the Niagara University, he was appointed clinical assistant to the chair of surgery, and subsequently held the position of lecturer in anatomy and laryngology. He at one time was a member of the surgical staff of the Sisters of Charity and Emergency hospitals. He first began the practice of general medicine, which he continued for a time, but afterward gave it up for the special field of laryngology, for which he had fitted himself in the schools of both this country and Europe. But recently he was appointed clinical professor of laryngology of the University of Buffalo. He was also associate editor of the *Buffalo Medical and Surgical Journal* with his father. He was a member of numerous medical societies, among which were the Buffalo Medical and Surgical Association, Erie County Medical Society, Medical Society of the State of New York, Buffalo Pathological Society, and Obstetrical Society. He was also a member of the Saturn and Thursday clubs. During the year 1890 he was secretary of the Laryngological Society of the American Medical Association, and he was recently chosen by the council of the American Laryngological Association for membership in that organization.

In political life he had taken a small part, having served two terms as civil service commissioner. He was removed from that office by Mayor Becker, along with Mr. Loomis, but was reinstated when Mayor Bishop was elected. This office he resigned about a year ago, on account of other business duties.

In 1887 he was married to Eva, daughter of Lars G. Sellstedt. To them two children were born, both of whom, with his wife, survive him. He was an active and hard-working member of his profession, and had until recently enjoyed the best of health. A week ago last Sunday he was taken ill, but was not compelled to take to his bed until Wednesday. It was then found that he was suffering from an enlargement on one side of the abdomen. On Saturday a surgical operation was performed, at which time nearly six ounces of pus were taken from the region of the colon. Blood poisoning had set in, and he failed rapidly, dying July 16.

DR. JOHN F. GROENEVELT, of New Orleans, and an Assistant Surgeon in the Marine Hospital Service, at the quarantine station at Chandeaur, died of yellow fever on June 29. The disease was probably contracted by the deceased in the course of his official duty, while he was inspecting a steamer from Brazil. He had already seen quarantine service at the Cape Charles and at the South Atlantic stations. He was a graduate from the Tulane University in the class of 1889, and was regarded as a young surgeon of talent and great promise.

It was believed at the Bureau that he was fully acclimated by having had the yellow fever, and the detail is understood to have been made at his own suggestion.

This is the fifth officer of this service that has perished from this disease in the last decade.

DR. JOSEPH PAYNE LOGAN, of Marietta, Georgia, died June 2, in the seventy-first year of his age. He was one of earlier vice-presidents of the American Medical Association, having held that office from 1860 to 1863. He was a Virginian by birth, was educated at Washington College, in State of nativity, and graduated in medicine from the University of Pennsylvania, in 1841. He practiced for a brief period at Baltimore, but made Atlanta the permanent field of his professional life. He was appointed Professor in the Atlanta Medical College, of the departments of Physiology and Principles of Medicine. He also edited the *Medical and Surgical Journal* of that city. He had been president of the Georgia Medical Association and of the Atlanta Academy of Medicine. He was for a time a member of the State Board of Health, in which capacity he contributed several valuable reports upon yellow fever and other epidemic diseases.

PROFESSOR F. W. SCANZONI died at Berlin, on June 13, in his seventy-first year. He was the well-known Professor of Obstetrics and Diseases of Women at the University of Würzburg, and author of one of the best of the pioneer "Lehrbuchs" on the sexual organs of women.

BOOK REVIEWS.

ST. THOMAS HOSPITAL REPORTS. New Series, Vol. xix. Edited by DR. HADDEN and MR. ANDERSON. Pp. 463. 8vo, cloth. London: J. and A. Churchill. 1891.

This handsome volume is not inferior to any of its predecessors—the actors may indeed change, but the stage, its wings, entrances and exits, and the shifting audience remain the same. The old story is retold, and interestingly too, of the great charitable work performed by this magnificent hospital, but it is the scientific portion of the book that will have the greatest interest for American readers. The first essay is one on the influenza epidemic of 1890, by H. P. Hawkins, M.R.C.P., which, although occupying 22 pages, the author has summarized in a single paragraph as follows:

"I believe, however, that we have gleaned nothing from this epidemic, save a more accurate knowledge of the rise of temperature, which we owe to the use of the clinical thermometer, and that we know less of the cause and origin than in the case of any other specific fever."

Fifteen hundred cases of influenza were seen by the St. Thomas' staff, and their records are utilized in this paper.

Mr. Mitchell Clark reports a case of total transverse lesion of the cord, upper dorsal region, in which the patient survived the injury ten months. After a painstaking necropsy, fully set forth, he concludes by saying "that in cases of lesion in the upper part of spinal cord, there must be retained some connection of its lower parts with the intercranial centres, even when sclerosis of the pyramidal tracts is present, in order that muscular rigidity and increased tendon reflexes may occur," which is a distinctly John Bull method of stating a proposition, but clear, if one will reformulate it with the same terms.

Dr. Robinson presents a tabulated report, with an analysis, of all the cases of radical cure of non-strangulated hernia from 1879 to 1890—numbering 64. The favorite operation, as shown by the record, was that of Mitchell Banks, and the results show that 43 of the cases operated on, subsequently communicated with, replied to the inquiries sent; of 18 cases of congenital herniæ, 14 replied, and all of these were "cured;" of 11 cases of funicular herniæ 8 replied, and all of these were "cured;" of five cases of femoral herniæ all replied, three were cured and two relapsed; of 22 cases of acquired inguinal herniæ, there were 14 replies, of these nine cases were cured, and five relapsed. It therefore appears from these statistics, that a much greater number of the congenital cases were cured than of those having acquired hernia. The mortality was 4 out of 64 cases. He clearly points out the dangers of removing large sacs *in toto*, and urges

that such sacs be divided high up, and the lower portion allowed to remain in the tissues unconnected with the abdomen.

Sir Wm. McCornac, in another part of the volume, gives his views on the subject, and thus concludes: "That in a large proportion of cases of inguinal hernia, especially those of congenital origin, a radical cure is possible, and that in femoral and umbilical herniæ of small or moderate size, the prospects of cure are good. Even where an absolute cure is not accomplished, a great gain is generally secured in the diminution of the hernial aperture, by which the retention of the hernia within the abdominal cavity becomes more practicable. Lastly, and most importantly, the operation, when properly performed, is scarcely dangerous to life."

There is a timely article by Mr. Leonard A. Bidwell, on the treatment of erysipelas by hypodermatic injection, and an interesting report by Dr. Cullingworth, of the In-Patient Department for Diseases of Women. Most interesting to physiologists is the report by Dr. Hadden and Mr. Ballance of the experimental observations on the brain of the monkey. These experiments were designed to show the effect *seriatim* of stimulation of the different convolutions, and were conducted at the Brown Institution, under the terms of a grant toward the expenses of the research by the Scientific Grants Committee of the British Medical Association. There is also an analysis of 708 cases of pneumonia by Dr. Hadden and others, and a very interesting account of forty-one fatal cases of osteo-myelitis by Mr. Mackins and Mr. Abbott, but our waning space admonishes that we must close our review of this volume, and in justice say to our *confrères*, "Well done! thou good and faithful." J. B. H.

HEREDITY, HEALTH AND PERSONAL BEAUTY.

By John V. Shoemaker, A.M., M.D., Professor of Materia Medica, Pharmacology, Therapeutics and Clinical Medicine, and Clinical Professor of Diseases of the Skin in the Medico-Chirurgical College of Philadelphia, etc. Phila. and London: F. A. Davis. 1890. Price, \$2.50.

Dr. Shoemaker has here given forth a work which may appeal to both the professional and lay mind; that is, it can be well understood by the intelligent non-professional, while much of its subject matter may well appeal to the physician. It may almost be termed a "popular science" treatise, and as such, will no doubt find welcome and an opportunity to do good. Dr. Shoemaker has certainly had a large experience, which admirably fits him for the proper handling of his theme. The book is pleasantly written, and is a credit to the publisher as well.

MISCELLANY.

AMERICAN ORTHOPÆDIC ASSOCIATION.—The fifth annual meeting of the American Orthopædic Association, will be held in the new reception room of the Arlington Hotel, Washington, D. C., September 22, 23, 24 and 25, 1891.

The office of registration of the Congress of American Physicians and Surgeons will be at the Arlington. The Association will be called to order daily at 9 A. M. Recess from 12 to 12.30 P. M. Adjournment at 2 P. M., or in time for the meeting of the Congress at 3 P. M. Exhibition of apparatus at the close of each day.

First Day—Tuesday.

1. The President's Address, Dr. A. B. Judson, New York.
2. The Orthopædic Work of the late Mr. Thomas, Dr. A. J. Steele, St. Louis.
3. Uniform Nomenclature in Orthopædic Surgery, Dr. W. R. Townsend, New York.
4. Two Cases of a Peculiar Type of Primary Crural Asymmetry, Dr. Henry Ling Taylor, New York.
5. On the Best Means of Preventing a Loose Joint, or Dangling Limb, after Resection at the Shoulder-Joint, with an Illustrative Case, Dr. W. R. Whitehead, Denver.
6. A Case of Spina Bifida with Partial Motor and Sensory Paralysis. Double Equino Varus and Purulent Bursitis, Dr. H. Augustus Wilson, Philadelphia.
7. Congenital Club-Foot, with Absence of Great Toe and Continuous Bones of the Instep, Dr. T. M. L. Chrystie, New York.
8. A Case of Club-Foot, Club-Hand and Multiple Joint-Deformity, Dr. William E. Wirt, Cleveland.
9. On the Use of the Wrench in the treatment of Club-Foot, Mr. Robert Jones, Liverpool.
10. Operation upon the Concave Surface in Talipes Equino Varus, Dr. B. E. McKenzie, Toronto.
11. The After Treatment of Excision of the Knee-Joint, Dr. John C. Schapps, Brooklyn.
12. Gonorrhœal Rheumatism and its Treatment; Primary and Secondary, Mr. B. E. Brodhurst, London.
13. Atrophy in Joint Disease, Dr. E. G. Brackett, Boston.
14. The Diagnostic and Prognostic Value of High Temperature in Chronic Joint-Disease, Dr. Robert W. Lovett, Boston.
15. On the Tests for Recovery from Joint-Disease, Mr. Robert Jones, Liverpool.
16. Apparatus for Making Traction, Dr. William E. Wirt, Cleveland.
17. Some Lateral Traction Fixation Hip Splints, Dr. A. M. Phelps, New York.

Second Day—Wednesday.

18. Rachitis in Adolescence, Dr. Bernard Bartow, Buffalo.
19. The Aspirator in Orthopædic Practice, Dr. Ap Morgan Vance, Louisville.
20. Congenital Misplacement of the Hip, with New Apparatus for its Treatment, Dr. A. M. Phelps, New York.
21. A Study of Atrophies, Dr. Roswell Park, Buffalo.
22. The Diagnosis of Pott's Disease, Dr. Robert W. Lovett, Boston.
23. The Differential Diagnosis in Pott's Disease, Dr. Geo. W. Ryan, Cincinnati.
24. Syphilitic Pott's Disease in Children, Dr. John Ridlon, New York.
25. Pott's Disease and Pregnancy, Dr. T. Halsted Myers, New York.
26. Paraplegia in Pott's Disease, Dr. E. G. Brackett, Boston.
27. Pressure-Myelitis in Pott's Disease, Dr. Albert Hoffa, Wurzburg.

28. Abscesses in Pott's Disease, Dr. Herbert L. Burrell, Boston.

29. Abscesses in Pott's Disease, Dr. W. R. Townsend, New York.

30. The Evacuation of Spinal Abscesses without Drainage, Mr. George Arthur Wright, Manchester.

31. Bilateral Lumbar Abscess, with a Case, Dr. James K. Young, Philadelphia.

32. The Benign Course of Abscesses in Pott's Disease under Efficient Mechanical Treatment, Dr. Newton M. Shaffer, New York.

33. The Value of Mechanical Treatment in Old and Neglected Cases of Pott's Disease, Dr. Henry Ling Taylor, New York.

34. The Mechanical Treatment of Pott's Disease, with an Exhibition of Apparatus, Dr. A. M. Phelps, New York.

Third Day—Thursday.

35. Malignant Disease of the Vertebræ Simulating Pott's Disease, Dr. A. B. Judson, New York.

36. Paralysis in Pott's Disease, Dr. Charles L. Scudder, Boston.

37. Prognosis in Pott's Disease, Dr. Samuel Ketch, New York.

38. Proposed Treatment of Pott's Disease by Wiring the Vertebral Processes, Dr. B. E. Hadra, Galveston.

39. The Operative Treatment in Spinal Caries, Dr. De Forest Willard, Philadelphia.

40. The Treatment of Pott's Disease with Especial Reference to the Early Stage, Dr. Bernard Bartow, Buffalo.

41. Pott's Disease in Adults, Dr. A. J. Steele, St. Louis.

42. Pott's Disease in Middle and Advanced Life, Mr. Howard Marsh, London.

43. Cervical Spondylitis, Dr. L. A. Weigel, Rochester.

44. The Prevention of Unnecessary Deformity in Pott's Disease, Dr. Royal Whitman, New York.

45. A Brief History of the Use of Suspension in Pott's Disease, Dr. Benjamin Lee, Philadelphia.

46. Recumbency in Pott's Disease, Dr. Ap Morgan Vance, Louisville.

47. Extension in Pott's Disease, Dr. B. E. Kenzie, Toronto.

48. Extension in Bed, Dr. Charles C. Foster, Cambridge.

49. Traction and Fixation in Pott's Disease, Dr. Reginald H. Sayre, New York.

50. The Treatment of Pott's Disease, Dr. V. P. Gibney, New York.

51. Comparative Value of the Present Modes of Treatment of Caries of the Spine, Dr. E. H. Bradford, Boston.

Fourth Day—Friday.

52. A Further Contribution to Typhoid Spine, Dr. V. P. Gibney, New York.

53. The Treatment of Congenital Dislocations of the Hip, Dr. E. H. Bradford, Boston.

54. On Elongation of the Ligamentum Patellæ as a Factor in the Production of Certain Knee Troubles and Difficulties in Locomotion, Dr. Newton M. Shaffer, New York.

55. Observations on Torticollis, with Particular Reference to the Significance of the So-called Hæmatoma of the Sternomastoid Muscle, Dr. Royal Whitman, New York.

56. Ten Cases of Excision of the Knee Joint for Disease, and their Lessons, Dr. Joseph D. Bryant, New York.

57. Rheumatic Spondylitis, Dr. George W. Ryan, Cincinnati.

58. The Definition and the Scope of Orthopædic Surgery, Dr. V. P. Gibney, New York.

59. The Relations of Lateral Curvature of the Spine, and Flat-foot, Dr. Paul Redard, Paris.

60. Pathological Anatomy of Lateral Curvature of the Spine, Dr. F. Beely, Berlin.

61. Means of Recording Rotation in Lateral Curvature, Dr. E. H. Bradford, Boston.

62. A Contribution to the Etiology of Lateral Spinal Curvature, Dr. Charles L. Scudder, Boston.

63. Modifications in the Treatment of Lateral Curvature, Dr. E. H. Bradford, Boston.

64. Spastic and Infantile Paralyzes, Dr. De Forest Willard, Philadelphia.

65. The Operative Treatment of Spastic Paralysis, Dr. L. A. Weigel, Rochester.

66. The Operative Treatment of Spastic Paralysis, Dr. Charles L. Scudder, Boston.

67. Additional Notes on Sacro-Iliac Disease, Dr. Benjamin Lee, Philadelphia.

Officers.—President, A. B. Judson, M.D.; Vice-Presidents, Ap Morgan Vance, M.D., George W. Ryan, M.D.; Corresponding Secretary, Samuel Ketch, M.D.; Secretary and Treasurer, John Kidlon, M.D., 337 W. 57th St. New York; Committee on Membership, E. H. Bradford, M.D., Arthur J. Gillette, M. D., Samuel Ketch, M.D., Benjamin Lee, M.D., L. A. Weigel, M.D.

AMERICAN DERMATOLOGICAL ASSOCIATION.—The fifteenth annual meeting will be held at the Shoreham Hotel, Washington, D. C., September 22, 23, 24 and 25, 1891.

First Day. Tuesday, September 22, 1891.

Business meeting (with closed doors) at 9:30 A.M. Report of Council. Nomination of Officers for the ensuing year. Appointment of Auditing Committee. Proposals for Active and Honorary Membership. Miscellaneous Business.

Morning Session at 10:30 o'clock. Report of Committee on Nomenclature, and discussion thereon.

Papers:

1. Dermatitis Hæmostatica, Dr. H. G. Klotz.
2. A Case of Lupus Erythematosus with Fatal Complications, Dr. W. A. Hardaway.
3. Report of a Case of Universal Erythema Multiforme, with colored portrait and specimen, Dr. L. A. Duhring.
4. An Unusual Case of Sarcoma involving the Skin of the Arm; Amputation; Recovery, Dr. F. J. Shepherd.
5. Multiple Sarcoma. History of a Case, showing Modification and Amelioration of Symptoms with large Doses of Arsenic, Dr. S. Sherwell.

Second Day. Wednesday, September 23, 1891.

Business Meeting (with closed doors) at 9:30 A.M. Report of Treasurer and Auditing Committee. Election of Officers. Election of Active and Honorary Members. Selection of Time and Place of next Meeting. Miscellaneous Business.

Morning Session at 10:30 o'clock. Report of Committee on Statistics.

Papers:

Discussion on Tuberculosis of the Skin:

6. Its Clinical Aspects and Relations, Dr. J. C. White.
7. Its Pathology, D. J. T. Bowen.
8. Its Treatment, Dr. G. H. Fox.
9. Thirteen Cases of Tuberculosis of the Skin, with their Treatment, Dr. J. S. Howe.
10. A Case of Lichen Scrofulosorum, Dr. J. Grindon.
11. Notes of a Visit to the Leper Hospital at San Remo, Italy, with Photographs, Dr. L. A. Duhring.

Third Day. Thursday, September 24, 1891.

Morning Session at 9:30 o'clock.

Papers:

12. The Treatment of Alopecia Areata, Dr. P. A. Morrow.
13. A Therapeutic Note on Alopecia Areata, Dr. L. D. Bulkley.
14. Morphia Atrophica of Wilson, Dr. R. W. Taylor.
15. The Treatment of Pruritus, Dr. E. B. Bronson.
16. Prairie Itch, Dr. L. N. Denslow.
17. Diseases of the Skin associated with Derangements of the Nervous System, Dr. W. T. Corlett.

18. Treatment of Chronic Ringworm in an Institution for Boys, Dr. L. A. Duhring.

Fourth Day. Friday, September 25, 1891.

Morning Session at 9:30 o'clock.

Papers:

19. Notes of a Case of Acute Dermatitis Exfoliativa, Dr. J. E. Graham.
20. Note Relative to Pemphigus Vegetans, Dr. J. N. Hyde.
21. A Study of Myosis Fungoides, with Report of a Case, Drs. H. W. Stellwagen and H. Leffingwell Hatch.
22. Lymphangioma Circumscriptum, with Report of a Case, Dr. M. B. Hartzell.
23. Remarks on Carbuncle, with Report of a Peculiar Case, Dr. H. G. Klotz.
24. Note on Erythema et Nævus Nuchæ, Dr. C. W. Allen.
25. A Case of Lichen Ruber, Dr. J. H. Grindon.
26. The Personal Equation in Dermatology, Dr. L. D. Bulkley.

Retirement of old officers and induction of those newly elected.

Officers for 1891: President, F. R. Greenough, M.D., of Boston. Vice President—L. N. Denslow, M.D., of St. Paul. Secretary and Treasurer—George Thomas Jackson, M.D., of New York.

THE AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION will hold its first annual meeting at the Hall of the College of Physicians, cor. Locust and Thirteenth Sts., Philadelphia, Pa., Thursday, Friday and Saturday, September 24, 25, and 26, 1891, under the Presidency of Dr. G. Betton Massey.

Physicians interested in the discussion of electricity in medicine, are invited to attend without further notice.

WM. H. WALLING, M.D., Secretary,
2005 Arch St., Philadelphia.

HORATIO R. BIGELOW, M.D.,
Chairman Executive Council.

JOSEPH O'DWYER, M.D., LL.D.—At the Commencement of St. John's College, Fordham, in June of this year, the honorary degree of Doctor of Laws was conferred upon Dr. Joseph O'Dwyer, of this city.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from July 11, 1891, to July 17, 1891.

Col. Charles Page, Surgeon, heretofore assigned to duty in the Division of the Atlantic, will report to the commanding General, Dept. of the East, for assignment to duty as Medical Director, and Lieut. Col. Charles T. Alexander, Surgeon, will report for assignment to duty as attending surgeon, New York City.

Asst. Surgeon A. B. Banister, U. S. A., granted leave of absence for fourteen days.

Major Ely McClellan, Surgeon, heretofore assigned to duty in the Division of the Missouri, will report to the commanding General, Dept. of the Missouri, for assignment to duty as attending surgeon, Hdqrs. Dept. of the Missouri, and examiner of recruits at Chicago, Ill.

Surgeon Bernard J. D. Irwin, U. S. A., relieved from duty at St. Louis, Mo., and ordered to Chicago, Ill., for duty as Medical Director, Dept. of the Missouri.

Asst. Surgeon Paul R. Brown, U. S. A., leave of absence extended one month.

Asst. Surgeon John J. Cochran, U. S. A., leave of absence on surgeon's certificate of disability extended three months.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending July 18, 1891.

P. A. Surgeon L. W. Atlee, ordered to the "Independence," James Shirley Hope, appointed an Asst. Surgeon in the Navy from July 10, 1891.

Surgeon Wm. Martin, detached from duty at the Marine Rendezvous, San Francisco, Cal., and from special duty in that city and granted leave until September 15, and then to be placed on waiting orders.

P. A. Surgeon M. H. Crawford, detached from the "Independence," and ordered to duty at the Marine Rendezvous, San Francisco, Cal., and to special duty in that city.

ORIGINAL ARTICLES.

NECROSIS OF THE MAXILLÆ, WITH A REPORT OF THREE CASES.

*Read in the Section of Surgery and Anatomy, at the Forty-second
Annual Meeting of the American Medical Association,
Washington, D. C., May 3, 1891.*

BY WALTER B. JOHNSON, M.D.,

OF PATERSON, N. J.

SURGEON TO THE PATERSON EYE AND EAR INFIRMARY, SURGEON
TO THE PATERSON GENERAL HOSPITAL, ETC.

Necrosis is the death of bone in mass with subsequent separation of the part, being analagous to gangrene of the soft tissues and differing absolutely in its physiology from caries, which is a molecular death of bone resembling the ulcerative process.

Necrosis occurs with considerable frequency in the maxillary bones, having a decided preference for the inferior maxilla, which it affects in about 65 per cent. of the cases; its selection of the lower jaw as a seat of infection is probably due to the comparatively limited vascularity and the absence of periosteal reduplication in this bone, and to its position being unfavorable to proper drainage.

The causes of necrosis of the maxillæ are ostitis, periostitis or periodontitis resulting from one or more of the conditions or diseases here enumerated.

By extension.	{ Dental ulceration. Alveolar inflammation. Alveo-dental inflammation.
By irritation.	{ First or second dentition. Eruption of wisdom teeth.
By disease	{ Syphilis. Exanthema. Scrofula.
By poisons.	{ Mercurials, systemic. Phosphorus, local. Arsenic, local. Chloride of zinc, local.
By traumatism.	{ Teeth extraction. Blows or falls.
By idiopathia.	

In maxillary necrosis from any cause the infection and the course of the disease are very similar, varying only in the location of origin and in the extent of the destructive action.

The inflammation may occur primarily in the osseous structure itself causing an excessive

engorgement with rapidly increasing stasis in the blood vessels, resulting, if not speedily relieved by antiphlogistic local and constitutional treatment, in a complete cessation of the nutrient faculty with immediate death of the entire portion of bone affected, and subsequent separation from its periosteum and exit through the soft parts.

This inflammation of the osseous body itself occurs more frequently as a result of the process of dentition. When occurring from this cause the effect is more prolonged in consequence of the continued irritability and excitability of the parts concomitant to this process.

If the inflammation originates in the periosteum or periodontum the resulting necrosis is apt to be less rapid or extensive, and occurs from the separation of the periosteum or periodontum from the osseous structure by a plastic hypertrophic exudation of osteophytes causing death of the bone from malnutrition, and accounts for the wonderfully perfect reproduction that is happily of so frequent occurrence after this disease. The periosteum is frequently destroyed in part during the progress of the disease, as also are the deciduous teeth and the permanent teeth germs, although disease may completely encircle a permanent tooth in its alveolar crypt without passing through its vascular sac or in any way affecting its formative tissue or interfering with the process of calcification, in which case the tooth may go on to a stage of complete development and be erupted, in the newly formed osseous tissue, at its natural point or at some point along the jaw which may have been designed for a tooth which was destroyed by the disease. The necrotic process is marked by four distinct periods.

1. The hyperæmic or stage of inflammatory engorgement.
2. The hypertrophic or stage of cacoplastic exudate, with formation of fetid pus.
3. The separative or stage of demarkation of bone with loosening and exfoliation of teeth.
4. The formative or stage of exit and reproduction.

The treatment should always be applied in strict accordance with the existing stage of the disease.

1. Active antiphlogistic internal medication and external application, blood letting, prompt

removal of any exciting cause or source of local irritation.

2. Early incision, antiseptic syringing, assistance in commencing separation of periosteum.

3. Antisepsis, constant syringing, tonics, removal of bone through the mouth in pieces or in mass without injury to the periosteal cradle, when exfoliation has occurred and it can be completely and readily separated from the periosteum and soft parts. To remove the body of the lower jaw, division at the symphysis is imperative.

4. Antiseptics, cleanliness, stimulating injections, continued tonic treatment and nourishment, while the discharge persists; Nature does the rest.

The prognosis is good as regards the question of ultimate recovery, although in patients of a scrofulous or syphilitic habit and in poor tissue builders the progress of the disease is slow, (from seven months to two years) and the destruction of tissue is often so extensive that a greater or less amount of permanent deformity results.

The usefulness, strength and natural motion of the jaw is generally maintained either by the formation of new bone if the periosteum is healthy, or in case material destruction of the periosteum has occurred by the formation of a fibroid cicatricial tissue of unusual strength supplying its place.

Case 1.—W. B., age 4, United States. Male. His family history is good on the paternal and maternal side; no history of disease of bone can be traced. For a little over a year before coming under observation he had trouble on the right side of his face. He had at first a swelling over the superior maxillary bone which assumed a bluish color, was attended by severe pain and a decided febrile movement coming on suddenly, and under hot paluvia and general antiphlogistic treatment almost entirely disappearing, only to reappear in the course of a few days or weeks.

Three months after the onset of the disease an external incision was made just under the lower eyelid and a considerable quantity of pus was discharged; the fistula thus formed continued to discharge up to the time of his first visit.

On examination found some tumefaction of the cheek and a permanent spot of ulceration just under the eyelid about over the orbital ridge, causing a marked ectropion as a result of cicatrization and adhesion, passing a probe through this opening dead bone was instantly discovered about the infra-orbital edge of the superior maxillary bone, extending downward towards the teeth and backwards towards the orbital plate of this bone.

An operation was advised and performed as follows: the patient being etherized, an incision was made in the mouth extending from the first bicuspid tooth backwards one inch and upwards towards the fistulous opening about three quar-

ters of an inch; a probe threaded with a seton of braided horse hair several strands thick was then passed into the incision and through the fistulous opening. This seton was fastened securely in position; one end passing from the mouth and the other from the opening, being retained for one week; after this time it was removed, the internal opening became permanent and the external closed in a few weeks.

The opening within the mouth was increased in size by the manipulation used in separating the periosteum from the bone and in removing placques of bone from time to time until all of the external alveolar plates of that side had come away.

About three months after the first examination, and fifteen months after the onset of the disease, a smooth prominence was detected by the probe high up and apparently just under the orbit. It was removed with difficulty; although not firmly fixed it had the size and shape of the crown and body of a second molar permanent tooth. It was devoid of roots and seemed to be in process of formation. It was very light and semi-transparent, having a very sharp edge, and within this edge and adherent to the tooth formative pulp; a large piece of dead bone was also removed at this time which formed the external wall of the antrum of Highmore, causing a profuse hæmorrhage, some of which was discharged through the nose; hæmorrhage from the nose occurred quite frequently during the progress of the treatment, subsequent to this time, as a result of passing the probe in search of dead bone. Inflammatory attacks had occurred on different occasions up to this last procedure and had been accompanied by profuse discharge of pus from the internal opening and on several occasions from the external opening also, but from that time on no more bone was removed and the sinuses were allowed to heal.

Eight years later, at the present time, the patient is strong and well nourished, has had good health and no trouble with his teeth, has a depression along the entire right side of the upper jaw due to loss of the alveolar plates. The lateral, eye, first bicuspid, and first molar permanent teeth are perfect and in good position, the second bicuspid is in position but entirely reversed, so that the external and internal surfaces of the tooth look from before backward. The second molar is absent. The cheek is adherent to the maxilla held by several cicatricial bands at the point of opening of the old internal sinuses. There is a slight scar under the eye and an almost imperceptible drooping of the lower lid, the cicatrices which caused the ectropion having been absorbed. The patient's present appearance would hardly suggest the possibility of so tedious and extensive a disease ever having existed.

D. M., a female, age 5, United States. Her

family on the father's side has been noted for longevity and strength and give no history of any infectious or hereditary disease. The mother is of an extremely nervous and excitable temperament, and on her side relates a history of pulmonary trouble, but not within her immediate family. There has been no history of bone disease on either side. The patient had always been healthy and was fat and robust, never having had any illness of importance until the onset of the present trouble, nine months previous to her coming under observation. When four years and three months old a swelling of the left side appeared and was accompanied by occasional attacks of pain. This swelling and pain was considered a result of ordinary toothache and was very much neglected.

Three months from the time of its inception, the tumefaction and pain having persisted and increased, an opening occurred on the inner side of the cheek near the angle of the lower jaw, through which considerable quantities of stringy pus was discharged. The opening and discharge had occurred after great febrile disturbance, swelling and pain; from this time until nine months after the disease first appeared, the history is a simple repetition of exacerbation of the swelling and return of a subsiding discharge through openings permanently established or through new openings occurring, and always being accompanied by febrile disturbance and pain.

First examined patient nine months after the onset of the disease. At that time there was great tumefaction of the face on the left side with external and internal points of opening or cicatrization.

The swelling was extremely hard and unyielding to pressure at any point, extending over the entire left side of the face and neck, and was not painful except when an attack of inflammation was coming on and pus was forming.

The child was unmanageable, and ether was administered in order that a proper examination could be made; on the outer side of the lower jaw at and in front of its angle several fistulous openings were discovered, into which a probe was passed disclosing some points of roughened bone. There were several external openings which communicated directly with the roughened bone itself, or opened into other sinuses within the mouth.

Two weeks after the above described examination, which resulted in a decided increase in the softening, redness and swelling of the parts, and an attack of cervical adenitis, she was advised to submit to an effort at removal of the dead bone, which was detected at the first examination. She was placed under ether and an incision about an inch in length was made extending from the angle of the jaw forward. Large quantities of fetid pus and a plate of bone the size of

a five cent piece were removed. This opening was made permanent by syringing, manipulation and applications, and during the three months following, there were removed from eight to twelve small plates of bone varying in size from a split pea to the little finger nail, and, also, two of the permanent teeth in process of formation; one had attached to it the formative pulp and was apparently healthy, the other had arrived at the stage of crown formation, was greenish and discolored and had the appearance of having been the original cause of the trouble and having probably acted as a foreign body for months.

The disease, after this operation, practically abated, although it was some weeks before the sinuses all closed, and the treatment was continued until that time.

Present appearance, eight years after the cessation of the trouble, patient strong and well nourished, has five scars about the angle of the jaw on the cheek, and a decided sinking and loss of tissue at the angle of the jaw and extending forward to the bicuspid teeth. The two molar teeth are gone, having been lost during the progress of the disease. The second bicuspid tooth came in, but decayed very shortly after and its removal was rendered necessary as it was also ulcerated; it had, however, ample root formation. The mucous membrane of the cheek is drawn towards the opening made at the operation by cicatricial bands, adherent to the reproduced portion of the jaw bone, which has changed its shape slightly at the angle in consequence of there being no teeth to oppose the upper molars.

The patient is rather a prepossessing child and is but slightly deformed as a result of her necrosis.

H. D., male, age 6, United States. Has a syphilitic history on the paternal side, which disease, as far as can be ascertained, was never contracted by the mother. Has no family history of diseased bone. Was in the enjoyment of excellent health, and had suffered from none of the diseases of childhood; at five years of age he had a moderate swelling of the face and toothache, so-called. The pain in the face and swelling increased to such an extent that in three days the parents were compelled to consult a dentist, who extracted the tooth supposed to be the cause of the trouble; the tooth drawn was only slightly decayed.

The drawing of the tooth was immediately followed by so rapid an increase in the swelling that on the second day thereafter the patient was unable to open his mouth.

Two months after this time, the child meanwhile having been very ill and suffering great constitutional depression, an operation for the removal of dead bone was performed, and five small scales varying in size were removed; all of these scales were very thin and rather longer than they were broad.

First saw patient one year and two months after the onset of the disease; there were several internal and external scars and openings where previous incisions had been made. The face was swollen and hard, but the inflammation was not and had not been very severe for a few weeks, the discharge of fetid pus was very great, an abundance of dead and roughened bone could be readily detected and it was easily movable when traction was made upon it with a bent probe.

Immediate operation was advised, the patient was etherized and a long incision made extending from the angle of the jaw nearly to the median line; the left half of the inferior maxillary bone was removed in two large pieces; a number of spiculæ of bone of different sizes also came away during the operation. The largest piece represented the body of the jaw and had connected with it two teeth not completely formed, slightly discolored, dead and not in process of formation, as there was no pulp adherent to them. The other piece consisted of the angle of the jaw, the condyle and coronoid process, and required for its removal sharp traction on the dental forceps, although it was undoubtedly separated from its periosteal cradle. After the removal of the bone mentioned the parts were thoroughly cleansed until no particle of dead bone could be felt at any point.

The child passed from my care after the operation but never had any subsequent attacks of inflammation and no dead bone was discharged or removed after that time, although the purulent discharge continued in decreasing amount for nearly a year. The long continuance of the discharge after all dead bone had certainly been entirely removed, is ascribed to the fact that proper antiseptic treatment was not continued, the parents being unable to persuade the child to undergo any further manipulation or application after the operation.

I have with difficulty been able to induce him to present himself for inspection at this time, over seven years after the trouble has passed away.

He is 13 years old, male. His general health is good, and has been so since the discharge stopped six years ago. During this time two teeth were erupted in addition to those at present in the jaw; one was on correct line but was partly decayed, the other was out of line and grew towards the cheek; the removal of this tooth was not painful but the line tooth was more firmly fixed and caused some pain on its removal. While these teeth remained in position they were a source of irritation, and also had a slight but constant purulent discharge from around their roots; after these teeth were removed, there was a great decrease in the tumefaction of the side of the face.

Inspection discloses a large scar on the neck,

the result of a cervical adenitis which had occurred in the early stages of the disease. The angle of the jaw is depressed and the side of the face is very much sunken at that point and in front of it nearly up to the median line. The lower jaw as reproduced is much shorter from before backwards than it was formerly, the central teeth striking about three-quarters of an inch behind the natural line, as shown by the position of the teeth of the upper jaw.

He has one bicuspid and an eye tooth on the diseased side, and also the central and lateral, which are in correct position; the eye tooth is misplaced, growing forward with most of its root exposed, and is partially decayed, and should be drawn. The bicuspid is in line and in position and seems to be a perfect tooth.

The jaw bone has made a complete reproduction but is composed on the diseased side of a comparatively small amount of osseous tissue; it is very useful, and strong enough for any of its ordinary uses.

The resulting deformity is much greater in this case than in either of the others, the sinking of the cheek and shortening of the maxilla giving the features a peculiar cast.

The study of the cases here reported and the history of other cases considered, indicate that incision and appropriate treatment in the early stages of the disease have a decided tendency to lessen its extent, while early efforts at removal of dead bone before separation has occurred are apt to increase the extent of the disease and resulting deformity, and may lead to a fatal termination.

CADAVER STUDIES ON THE REMOVAL OF THE SEMILUNAR GANGLION THROUGH THE FLOOR OF THE SKULL.

Read in the Section of Surgery and Anatomy, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY EDMUND ANDREWS, M.D., LL.D.,
PROFESSOR OF CLINICAL SURGERY IN CHICAGO MEDICAL COLLEGE.

The horrible severity of pain in certain trifacial neuralgias is such as to drive the patient to the verge of suicide. Most of them are relieved for a period of one or two years by operations already well known, and a few are cured for life, but the majority relapse, because the neuritis has progressed to the semilunar ganglion, and hence nerve sections and stretchings below that organ relieve only temporarily. I have formerly shown that this relief can be repeated at least several times, by reopening the wound and pulling upon the cicatrix to which the stump of the nerve is attached, thus subjecting the stump and the ganglion itself to repeated stretchings, but I have

little faith that the cure can be indefinitely repeated by this process.

I long ago concluded that the disease, in most cases, commences as a progressive neuritis excited by a decayed tooth, and extends upward into the ganglion itself, and hence that nothing less than the removal of the ganglion will effect a cure in the most obstinate cases. About a year ago, I commenced cadaver studies to see if I could devise any safe operation for the removal of the offending organ. It appeared six months later that Prof. Wm. Rose, of King's College Hospital, London, was independently considering the same question, and since that time he has performed the operation twice on the living subject, with success, thus fairly earning the credit of priority in point of time.

My experiments upon the cadaver, however, have interested me greatly, and throw much light on the best routes and methods of procedure. They also show that about six principal variations are possible in the plan of the operation. Cadaver studies are specially important, in this operation, because we cannot test and perfect the technique upon the inferior animals, since there is no species having a cranial anatomy near enough to that of man to answer the purpose.

The fifth, or trifacial nerve, emerges from the side of the pons Varolii as a rather large flat, striated band, and runs forward over the crest of the petrous portion of the temporal bone near the apex, where it enters an opening in the dura mater. This tough membrane, on the anterior slope of the petrous portion of the bone, divides into two layers, and contains the ganglion between them, so that the latter is, as it were, encapsuled in a flattened cavity of the dura mater about the size and shape of a small Lima bean. The under side of the ganglion lifts easily from the floor of the capsule, having a bursa under it, an arrangement which facilitates separating it from the underlying carotid artery, but the upper surface is very firmly adherent to the roof of the capsule, so that even a curette can scarcely dislodge it. This arrangement adds greatly to the safety of the removal of the ganglion.

Out of this capsule the three branches of the nerve run, and the largest one, the inferior maxillary, passes downward and outward through the foramen ovale, and becomes the guide of the surgeon to the capsule of the ganglion. It is sheathed with a stout prolongation of the dura mater, which withstands pretty strong traction without rupture.

Besides several small twigs, the inferior maxillary divides into two main trunks, the dental and the gustatory.

The semilunar ganglion, or rather the under side of its capsule, lies in part directly upon the internal carotid artery where that vessel emerges obliquely from the petrous portion of the tempo-

ral bone, and its inner border is in close relation with the curve of the artery, where it enters the cranium, and also with the cavernous sinus, so that care must be exercised not to wound these vessels.

Diagram of part of the relations of the semilunar ganglion.
A A A.—Portion of skull.
J.—Condyle and ramus of jaw.
S.—Semilunar ganglion seen edgewise.
C.—Internal carotid artery.
K.—The double dotted line represents that layer of the dura mater constituting the roof of the capsule of the ganglion. The white line between the ganglion and the artery is the under layer or floor of the capsule.
O.—Foramen ovale at exit of inferior maxillary nerve.
D.—Dental branch.
G.—Gustatory branch.
M.—Mylod branch.

This cut is a diagram only, to show certain relations, and not a precise section.

The ganglion is therefore in a very inaccessible location, being inside the skull, near the centre of the cranial floor, and in dangerous relations with great vessels—facts which have heretofore ruled it out of the field of operative surgery.

A closer study of the parts shows, however, that boldness and skill can storm the citadel. The point of approach must be at or near the foramen ovale, but in order to operate in such a location we must, by certain preliminary steps, uncover the parts, so as to see them with the eye, touch them with the finger, and attack them by a precise and unerring use of our instruments.

Fortunately, there are infallible landmarks to guide us to the foramen ovale, as a study of the topography will show.

My studies on the cadaver show the possibility of six forms of operation:

1. Prof. Rose's first operation, which was done by him six months ago. He uncovered the foramen ovale by excising the whole of one superior maxilla, thus getting at the parts from the front. He inserted the centre pin of a small trephine

into the foramen, and took out a button of bone surrounding it, and contrived, through the opening thus made, to extract more or less completely the ganglion.

The base of the skull seen from beneath.

O.—Foramen ovale.

S.—Foramen spinosum, for middle meningeal artery.

P.—Pterygoid ridge.

T.—Place of applying trephine in operation No. 3.

The patient's eye seems to have suffered some injury, for it became inflamed after the operation, and had to be enucleated, but the neuralgia ceased, and at the latest advices had not returned.

2. Rose's second operation was done last January. The method of uncovering the field of operation is very ingenious. Instead of removing the superior maxilla, two perpendicular incisions are made, one a little in front of the ear, and the other at the anterior extremity of the zygomatic arch, the posterior one commencing at the height of 2 inches above the zygomatic arch, and extending as low as can be done without severing the duct of Stenon, or more properly of Stenson. The anterior incision commences at the same height and extends a little lower than the poste-

rior one. A horizontal incision extends along the zygomatic arch, connecting the other two. The zygomatic arch is now sawn off at each extremity, and turned down, carrying the attached masseter muscle with it. This uncovers the coronoid process of the lower jaw, which is sawn off at its base, and turned up upon the temple with the temporal muscle attached.

This uncovers the deeper parts, which are carpeted with a loose connective tissue containing, in most instances, the internal maxillary artery, with many smaller vessels; yet in some cases that artery takes a deeper course, running internal to the external pterygoid muscle. The connective tissue being drawn aside or snipped away, and the artery or arteries ligated, if necessary, the short and thick external pterygoid muscle will be seen, running horizontally from the external pterygoid plate backward to the neck of the jaw. Usually the internal maxillary artery comes out from the inner side of the neck of the jaw at the lower border of this muscle, and winds forward and upward around its external border. Carefully clearing away the connective tissue below the muscle, the large inferior dental nerve will be found, running down from the inner side of the muscle to the inferior dental foramen in the centre of the ramus of the jaw, and a little in front of it, the equally large gustatory branch, on its way to the tongue. These unite higher up into one trunk, which can be traced, with a little patience, up to the foramen ovale about $1\frac{1}{2}$ centimetres forward and inward from the inner border of the condyle of the jaw. By feeling for the sharp edge of the external pterygoid plate, and tracing it up to its junction with the base of the skull, it will be found to lead exactly to the anterior extremity of the foramen ovale, so that we have two guides to the orifice, the great nerve, and the sharp edge of the external pterygoid plate. If the external pterygoid muscle is thick and voluminous, it may become necessary to divide it near the neck and retract it with a suitable instrument, so as to uncover the foramen. The axis of the foramen has such a direction that a line drawn from the centre of the coronoid process upward and inward through the centre of the foramen, passes just beyond it into the centre of the ganglion itself.

The trephine is now applied, but owing to its position being oblique to the floor of the skull, the crown of the ordinary instrument strikes the bone, without the centre-pin being able to reach the foramen, and consequently the saw cannot be steadily worked. To overcome this, the centre-pin must be capable of being protruded 2 centimetres, and have the end round and blunt, instead of sharp, and be withdrawn as the saw progresses, so as to run no risk of entering the skull too far, which would endanger the carotid artery. The centre-pin is also made about one-

half the diameter of ordinary centre-pins, otherwise it will be sometimes too large to enter the foramen. As the crown of the saw advances, the pin is drawn back. Prof. Rose uses a trephine of $\frac{1}{2}$ inch inside diameter, like the specimen here shown. If this is done, it must not be advanced too far, otherwise the inner side of the crown will come directly upon the carotid artery, before it enters the cavity of the skull. When the inner half has cut a little way in, remove the button, and clear away needed portions of bone with other instruments.

View of relations of the nerves.

Z.—Zygomatic arch and masseter muscle turned downward.

T.—Temporal muscle and coronoid process turned upward.

P.—External pterygoid muscle.

N.—Inf. dental and gustatory nerves. Their continuation upward behind the pterygoid is intimated by dotted lines. The emergence of the common trunk from the foramen ovale is at the left of P. and covered by the muscle.

A.—Internal maxillary artery.

The extra length of shaft is to enable the handle to clear more easily the face and jaw, but still the ordinary length can be used.

The ganglion is in the bottom of the hole left by the instrument, and can be removed by curetting and by a small hook-shaped bistoury devised by Prof. Rose, assisted by a blunt hook. The carotid artery lies in contact with the ganglion on the face that looks downward, backward and inward—corresponding to the anterior slope of the petrous portion of the temporal bone. The vessel also curves around the upper and inner border of the ganglion directly in line with the axis of the foramen ovale, so that instruments must not be pushed too far in that direction, for if advanced too deeply, the crown of the trephine will cut the artery.

3. From careful dissection, and experimentation upon the cadaver, I am convinced that the

following plan is better than either of the others:

Reflect the masseter and temporal muscles as before. Expose the external pterygoid muscle, divide it near the condyle, and draw it out of the way with a suitable retractor. You now have a considerable area on the base of the skull, where there is no important organ to be wounded. This is a smooth triangle, having the pterygoid ridge of the temporal bone as its base, and its apex a little beyond and including the foramen ovale. One head of the external pterygoid muscle arises from this clear area, which should be dissected up and retracted, or snipped out. This will give

A. A. A.—The skull.

S.—The semilunar ganglion.

O.—The foramen ovale.

J.—The ramus of the jaw.

T.—The trephine with the blunt center pin in the foramen.

C.—The carotid artery.

you a third guide to the foramen ovale, for if you clear away the tissues from the bone in a direction forward and inward from the inner border of the condyle, you will come unerringly, at the distance of about $1\frac{1}{2}$ centimetre, to the outer side of the foramen, which is an opening about $\frac{3}{4}$ of a centimetre in length, so that it need not be missed, even if the nerve had been torn or cut away by any accident. This clear space is over 2 centimetres in diameter, and affords abundant room for a 2 centimetre trephine, as shown at T, Fig. 2. Backward and outward from the posterior end of the foramen ovale, and at the distance of about $\frac{1}{2}$ centimetre, the middle meningeal artery enters the skull through the foramen spinosum, so that, if meningeal hæmorrhage occurs in the use of the trephine, it can be stopped by pressure of the tip of the finger at this point, or by ligature, or by plugging the foramen spinosum.

Also when the button of bone is withdrawn, the artery can be seized through the trephine

hole, since it lies on the external surface of the dura mater.

pterygoid ridge, and remove a large button of bone. Then raise the dura mater from the floor

Curved and blunt pointed bistoury, modified from that of Rose.

Now apply a medium-sized trephine at the point marked with a black circle in Fig. 2, and carefully remove the included bone, setting the inner edge of the saw within 3 or 4 millimetres of the outer edge of the foramen ovale. Next take a narrow guage forceps and nip away first the isthmus of bone between the trephine hole and the foramen, and then, drawing the nerve outward into the trephine hole, nip away the inner border of the foramen. By a good artificial or natural light, you now see well exposed a pretty large ovate area of dura mater, with the large inferior maxillary nerve emerging from its further portion. The sheath of the nerve here is very strong, so that it can be freely pulled during the further manipulations. Now peel up the dura mater from the floor of the skull under the ganglion, going a few millimetres beyond the locality of the foramen ovale. This lifts the ganglion with the membrane, it being included between the two layers. Next seize the nerve, or the stump of it, near the opening, with narrow forceps, and draw it outward. Dissect off the dura mater from its posterior or further surface of the insertion of the nerve, and you will come into the capsule and the bursa between the gland and the floor of the capsule. Extend the opening of the capsule to the right and left somewhat freely, and with a careful use of Rose's knife or a very small blunt-pointed and curved bistoury, divide the origin of the superior maxillary nerve, and if possible of the ophthalmic branch. The latter lies very close to the cavernous sinus.

Now have an assistant lift the dura mater, while another one draws the nerve inward, and you will be able to open the dura mater and very slowly to dissect the ganglion away from its firm adhesions to the roof of the capsule. This dissection is a little tedious, on account of the firmness of the adhesion, but patience will accomplish it, and if one or more slight cuts occur through this upper layer of the capsule of the dura mater, no dangerous results will follow. Indeed, it might perhaps be well to take curved scissors, and cut out a small circle of the roof of the capsule and take it away with the ganglion, thus shortening the operation. This operation admits of splendid illumination, and enables one to see clearly the steps of the dissection.

4. A fourth method is possible on the cadaver, but less easy than the third. It is to commence as in the previous operation, but to set the centre-pin about a centimetre farther out on the

of the skull, working inward until the ganglion is lifted and the finger feels a large probe inserted into the foramen ovale. Now open the capsule and patiently work out the ganglion, guided by feeling rather than by sight.

5. A fifth plan can be carried out as follows: Leave the zygoma and the coronoid process untouched. Raise a semicircular flap of scalp and temporal muscle from the temporal fossa in such a way that a large trephine can be set on the bone, with its lower edge close down to the zygoma, much as in Stephen Smith's operation for tying the middle meningeal artery inside the skull. Remove the button and, making a flap in the dura mater, insinuate a peculiarly shaped curved spatula under the convolutions of the brain, and lift them from the floor of the middle fossa. The ganglion lies on the anterior slope of the petrous portion of the temporal bone, with its lower edge about $2\frac{1}{2}$ centimetres from the lower edge of the trephine hole. Pass in the finger under the arch of the spatula, run it along the petrous portion to identify the locality of the ganglion by its softness. Withdraw the finger, throw in a strong light, dissect out a circle of the roof of the capsule of the ganglion, and use the hook-shaped bistoury, bent scissors and curette to sever other attachments.

This plan temporarily compresses the brain, and makes some unavoidable contusions and slight wounds of the convolutions, but it is not very difficult. It would be doubtless more dangerous than either of the others, and therefore is not to be preferred in our present state of knowledge.

6. The sixth and last method is to make an incision from the anterior edge of the temporal muscle down to the anterior slope of the coronoid process, and saw off the anterior end of the zygoma. Next saw off the posterior end through a small opening in the skin. Then saw off the ramus of the jaw from the middle of the anterior slope of the coronoid downward and backward to near the angle of the jaw. Raise this flap of skin, muscle and bone as on a hinge, and turn it back over the ear. My first hope was to uncover the deeper parts in this way without sacrificing any bone, but the result was to pry the condyle of the jaw inward, bulging the external pterygoid before it, and effectually covering the foramen ovale from sight; hence, if this plan is adopted, it is necessary to excise the condyle, draw away the external pterygoid, and divide part of the internal pterygoid, in order to follow the inferior maxil-

lary nerve into the foramen. This and the plane surface of bone external to it being thus exposed, the operation is finished either as in No. 2 or in No. 3. The loss of the condyle is an objection in this case, just as the loss of the superior maxilla is in No. 1. On the whole No. 6, though mechanically feasible, cannot be recommended.

Of the whole six, I give the preference to the third, which uncovers the parts as in Rose's second operation, but applies the trephine at a different spot.

In the two cases operated on by Prof. Rose, the first lost the eye by inflammation following the operation, due perhaps to accidental injury at the resection. In the second case the professor informs me that the eye, three months after the operation, was in good condition, and was recovering its lost reflexes. Both patients were relieved of their pain, thus far, but more time must elapse to demonstrate the permanency of the cure.

As the eye is deprived of sensation, the patient must be taught to care for it and protect it. In the same way one side of the tongue being benumbed, it must be guarded from being wounded by the teeth.

A neurotomy of the fifth nerve on the proximal side of the ganglion can be performed, without removing the latter. If you proceed as in operation No. 3 till the button of bone is removed, and then open a flap in the dura mater external to the ganglion, the convolutions can be lifted, and a knife with a double curve and blunt point can be passed over the crest of the petrous portion of the temporal bone, and made to cut the nerve where it enters the capsule of the ganglion. This operation is possible, but does not seem advisable. It is not best to replace the button of bone in these cases, because a certain portion of such pieces necrose, and the deep location renders the subsequent extraction of the dead fragment difficult.

On the whole, the removal of the semilunar ganglion is a slow and rather complicated operation, but it is not very dangerous. It is to be employed without hesitation whenever a trifacial neuralgia is so severe and so incurable that the patient has no reasonable hope of relief from extreme pain by other measures.

Time only can show how many will be permanently cured. From the nature of the case we should expect that the cured cases would be a large majority, but that in a few the brain itself may be the seat of disease, and baffle our efforts. If the brain is the seat of the trouble, we can usually determine it by the coincident presence of other cerebral symptoms, and thus avoid operating upon hopeless cases.

In making these researches upon cadavers, I am indebted to Profs. Wyllys and Frank Andrews for valuable assistance.

No. 6 Sixteenth St., Chicago.

PERITONITIS, FROM A SURGICAL STANDPOINT.

Read before the Section of Surgery and Anatomy, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY M. PRICE, M.D.,
OF PHILADELPHIA, PA.

There is no more important subject presented for our careful consideration, or more deserving our most earnest thought, than peritonitis.

It is practically a new field for investigation; few of us comprehend its magnitude, or the importance of the work now being done. Idiopathic peritonitis is a myth and a delusion. The error has been that symptoms have been mistaken for the disease, and when relieved, a cure is accredited to some special form of treatment. Vomiting and tympanitis with pain does not necessarily indicate peritonitis.

There are many conditions of the digestive tract that will give all these symptoms, yet no peritonitis be present. And you may have peritonitis without pain, without tympanites, in fact, almost devoid of symptoms, yet have many ounces of purulent fluid in the peritoneum.

Peritonitis always has a cause, and if the case be properly investigated, we can find it. For so serious a condition, it is one of the most curable diseases we are called to treat. That is, if we investigate the cause, and remove it. And then again, it is most wonderfully submissive to bad treatment. Improving again and again under the opium treatment, which is the worst of all, for it blinds the practitioner to the dangerous forms when they do appear for proper treatment, and where nothing but the proper treatment will save life. I marvel at the great credit men give to the opium treatment of peritonitis. And when recovery takes place, credit all to their treatment, with not one thought of the wonderful protective power of nature to guard her inner work.

Have they treated the condition, the actual disease, the exciting cause? No, in most cases they have not even investigated to find the cause; but have contented themselves with the thought that their patient is now all right, notwithstanding the fact that the patient suffers repeated attacks, until there comes a time when the operating table or the post-mortem table reveals to the wondering practitioner a cause. Thanks to the surgeon, we do not have to resort to the post-mortem to find what has given our patient peritonitis, or the way for their relief. I purposely avoid quotations from standard works; all of you are familiar with them, and as most they say does not interest us at the present day, I will not trouble you with either their pathology or their so-called treatment, with opium as their sheet anchor. I except those writers of a century ago: Dewees, and that great teacher and writer, George B. Wood. How strange that medical men are so

forgetful of the teachings of these masters of their day! Men follow the fashions of their professors.

Peritonitis is a disease so peculiarly surgical in the development of its pathology, and the perfection of its treatment, and the utter extermination of its mythical origin, that we do not any longer have to resort to the dead-house for our knowledge of its history. Ante-mortem examinations have taken the place of the dead-house pathology of only a few years ago. We all remember to have made such examinations that, to-day, by operative measures, the patient could have been saved. Its cause removed, and thereby forever preventing the return from the same point of infection. For some of these cases passing through my hands have had as many as five different attacks, and had it not been for surgical aid they could not have been saved.

The peritoneum in health is a lymph sac enclosing every organ in the abdominal cavity. There are a few exceptions to this rule, but of slight moment in the consideration of the subject of the inflamed condition. A peritonitis may be partial, or it may include the entire membrane; a general peritonitis. The symptoms are mild or severe, partial or general, owing to the nature of the irritating cause. It will, in most cases, begin with a chill, but not always. It usually has at the beginning a high temperature, but not invariably. Pain on pressure is one of the best, and by all odds the most valuable symptom we have to guide us to a correct diagnosis. Yet, the pain may be so slight that the patient may not call our attention to its existence. The pulse may be quick from the start, and, after a short period, become hard and tense.

There is no single symptom that can be depended upon, many patients when operated upon having a pulse as high as one hundred and fifty, and they made just as rapid recovery as those whose pulses were at eighty, full and strong. In most cases, however, the pulse is thin and thready. Tympanitis is not a constant symptom, though one that gives a great deal of trouble, and adds wonderfully to the risk of the patient.

The expression of the face, next to pain, is probably one of our best diagnostic symptoms; it is one of great anxiety and alarm expressed in every feature; they seem to have aged many years in a single day. The features seem pinched and prematurely old. The bowels are always constipated, unless we have a case of peritonitis resulting from dysenteric ulceration, or from some complication of the intestinal tract. The old treatment of putting the bowels in splints by opium was certainly unnecessary, as it had already been done most effectually by the paralyzing influence of the inflammatory condition.

Then, to properly understand the condition of

our patient, we must investigate every organ in the abdominal cavity; the pelvis through the bowel, if it be a man, and through the vagina, if a woman. We can thus derive great help and often a perfectly clear understanding of the condition, when we can get it in no other way.

In almost all the cases to which we are called to remove the source of infection, the effort of nature to limit its destructive ravages are well marked by protective lymph walling in the diseased portion. In the many examinations we have made on the operating table of peritonitis, the conclusions that have been forced upon us by such investigations prove to my mind that there is always an irritating and demonstrable cause for all cases of peritonitis.

I have never found a case without positive indications of destructive changes going on in the infected parts, the contents bathed in serous sero-purulent fluid, with adhesions varying from slight to those so firm that it was easier to tear the surrounding tissue than the adhesions, with small collections of pus in many different places walled in by the peritoneum in its efforts to prevent general infection. Young and old alike suffer from its ravages. Both sexes do not suffer alike, for the reason that women are by all odds subjected to many times the dangers of this condition by causes peculiar to their sex.

The older writers did not give peritonitis a separate place, but associated it with other lesions within the abdominal cavity, clearly showing they did not endorse the theory of its idiopathic origin. How near do they come to the pathology of the present day?

I have, in the last five years, operated or assisted with five hundred operations for the cure of peritonitis; all of them so serious that life without operative treatment could not have been saved. All of them had been treated by medical men of the best standing in the profession, and at least four-fifths by firm believers in the opium treatment. Many of these patients had suffered more than one attack, some of them as many as five before they had come to that point of their disease where some radical measures had to be resorted to to save life and remove the point of infection. Beside this, I have examined some twenty, who were past all surgical aid when I was called to their side, and in every case a well-defined cause was found for all the trouble. There was not a single case examined in all this long series of cases without lesions of such serious nature that they must by their very character have proved fatal at no very distant day. There was not one case of idiopathic peritonitis in the list, though more than one-third of them had been so named by good men. In the month of December I had the good fortune to assist at eleven bad cases of localized and general peritonitis, and operate four times myself, all of which

must have been fatal very soon, some of them having had several attacks.

The advocates of the opium treatment speak of the disappearance of the distention, and softening of the abdomen after a number of days. In our experience if the case be one of true peritonitis, and the symptoms do not improve under saline purgation, and the temperature come down below the pus standard in from three to five days, we at once decide to remove the cause by operative measures, and I have yet to regret the use of the knife in these cases, but I can say I have to regret some of the delays I have been persuaded into by the fears of other counsel in the cases. Prompt purgative treatment in the beginning of peritonitis, by the saline purgation or the mild chloride of mercury, to clear up the case in the very beginning, and then when you have done all this, and there is no improvement you must, in the present light that surgery has thrown on the subject, operate.

Peritonitis from other causes, the indications being the same, show the great tolerance to manipulation and contact with the poisonous pus in which every known form of microbe must have existed by millions, where large flakes of inflammatory lymph had to be removed by scissors, where the adherent bowel was detached from the pus sac, and yet with all these complications and with all the microbes and pus there was not one case of peritonitis following operation in the whole series of over five hundred cases. What were the causes for all these five hundred cases of peritonitis? all had a cause, and the cause was found in every case. To enumerate all the causes that might cause peritonitis would be a most thankless undertaking, for they are innumerable. The vast area and the important glandular organs enclosed in the peritoneum, add their mite to the list, but by all odds the most prolific cause of peritonitis comes from a diseased condition of the uterine appendages; these offer a direct way of entrance to some of the most virulent poisons to which women are exposed. This mode of entrance and the subject to which it relates, and its influence in the formation and production of peritonitis, local and general, has been the subject of many papers, I might say volumes. I need not here mention it more than as a prominent cause.

Second in importance is that of appendicitis. Here is a prolongation of the large intestine, unused, a place for the lodgment of foreign substances and concretions of its own formation, with none of the cleansing and purifying conditions which other portions of the bowels are constantly subjected to in the constant moving of the contents, and the contact of the secretions of the digestive fluids of the different glands, which have by Nature been placed to correct just that condition to which the appendix is exposed,

with no power to remove. From this source come many of the causes of peritonitis.

In the treatment of peritonitis in the past great latitude was allowed, and medical men made the most liberal use of the privilege in the use of opium and its preparations. Some delighting in the extracts, others a mixture with other drugs, all trusting with implicit faith in morphia in large and repeated doses as much as one grain every two hours, others recommending as much as four hundred grains in the twenty-four hours of the pure extract of opium. Others prefer the liquid preparations, they in their turn mix and blend them in a manner and with a faith as to their marvellous curative qualities that some of us are unable to understand. Great weight is laid on the indications for the use of opium; one observer is satisfied when the patient is relieved of his pain, another not content with this condition alone gives opium for its effect, and his measure of guidance is the respirations; when they have been reduced to ten or twelve per minute, he then considers his patient safe. Then when opium does not bring the result so earnestly sought after, they use a combination of calomel and opium; one they say to stop the secretion of bile, and the other to start the bile on its usual way. They report many happy results, many patients saved by this most ingenious blending of the incompatible. The other treatment contemporary with that just alluded to of peritonitis, such as poultices, blisters, turpentine and the warm application, all to my mind indicate what the practitioner expected to be the result—the formation of pus. This is just the treatment he would give to an existing or threatened abscess in any other portion of the body. How long will this state of things last! Can we not offer them some more encouraging method of treatment? I think we can. I hope the day is past when we will follow blindly the teachings of any man or set of men, but will weigh the facts as they are given us, and from them and our own knowledge of the subject, build a new and more comprehensive treatment than that of the past, which I fear is now almost the only treatment for this most destructive disease when not properly treated and by the most energetic and rational methods.

My firm belief is that when called to a case of supposed trouble to make at once earnest search for the cause, and, if found, to remove it at once, is the proper course to pursue. If the cause be not apparent, then clear up the case with saline purgatives, and when not able to do so, then abdominal section. And, as I have said before in this paper, you will never have cause to regret it. Prompt adherence to this rule has been the practice of all those men who have learned their pathology at the operating table instead of the dead-house.

The present way of treating these cases was also the old way used by the majority of the profession. The very first thing is opium in some form to relieve the pain, as they will tell you in most cases without looking for a hernia, or any other cause for the trouble. Pain is the only symptom complained of, so most men are content when the patient is relieved of that.

I have been called to a patient suffering from strangulated hernia, with all the symptoms of peritonitis, and the medical attendant not aware he had anything more than a case of idiopathic peritonitis to deal with. I will venture to say, that if all the medical men in this city could be asked what the first thing they would do for a case of threatened peritonitis, they would say relieve him or her of pain by opium. It is the almost universal rule, notwithstanding the stress laid on the great danger to the patient in such treatment.

There is still another and most important reason for early treatment in these cases. We all know that one of the favorite and accepted theories of the introduction of tubercle bacillus is through the stomach in its deranged and diseased condition from any cause, and in this way into the general circulation to be deposited in that portion least able to resist its ravages. In these cases where we have a subacute inflammatory condition with large deposits of inflammatory matter of low vitality, where the circulation is in a most unsatisfactory condition, where the thermometer indicates a temperature in which these little bodies grow and flourish to a most alarming extent, tissues of low vitality are fastened together. What better culture ground or condition could even a pathologist wish for in which to feed and grow his medical menagerie. Be this true or not, the fact still stands forth that many of these chronic cases die of tuberculosis.

A NEW OPERATION FOR HARELIP.

Read in the Section of Surgery and Anatomy, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 5, 1891.

BY CHRISTIAN FENGER, M.D.,
OF CHICAGO, ILL.

In all forms of harelip (*labium leporinum*), whether single or bilateral, whether partial or total, whether combined with cleft inter-maxillary bone or not), we find not an excess, but rather a defect of labial tissue, mucous membrane, prolabium and skin. The two portions of the upper lip, when brought together, are too small to form a lip of normal shape; it would require the interposition of a triangular piece of lip with apex towards the nose and base toward the border of the lip, to obtain at once a lip of normal shape. The tissue defect is greatest in the skin, less manifest in the mucous membrane and prolabium;

still in the majority of cases of complete harelip, the defects in these tissues also may be considerable.

It would thus seem natural to select a method of operating by which no tissue should be lost. In all the older methods the so-called "freshening" of the surfaces to be united requires the removal of at least a part of the prolabium, in some more, in others less, at the best, as in the method of Nélaton for small harelip, a displacement downward, to form a projection which must either disappear by retraction and atrophy, or be removed, if present in excess, by a secondary operation.

About five years ago I was led to consider this question in a case of double harelip with rather defective lateral portions, in which I operated after the old method and suppuration with consequent non-union took place. At the next attempt at union, the increased defect of tissue made union still more difficult than at the first operation. I therefore concluded to operate in my next case without the removal of any tissue, so as to have at least not lost anything in this respect if suppuration and non-union should make one or more later operations necessary. When I commenced to operate in this way I found it necessary to apply a separate row of sutures to the prolabium before bringing the edges of the skin together, thus closing the wound toward the mouth, and I soon found this to be a protection against infection.

I have since that time never had any reason to abandon this method for any of the older methods.

1. OPERATION FOR UNILATERAL HARELIP.

1. *Incision.*—The incision is made at the border of the skin and prolabium, four to six millimeters or two to three lines deep, care being taken to guard against opening through the mucous membrane into the mouth.

It is necessary to draw the lip down in order to procure sufficient tension for the knife to divide the tissues; this traction causes anæmia of the border of the lip, making the line between the white skin and red prolabium indistinct. It is necessary to be careful to have the incision precisely in this line, because a small margin of prolabial tissue left with skin will, as I have seen in one case, leave a red brim along the line of union, necessitating a secondary operation for cosmetic reasons. (Figure 1.)

The length of the incision downward and outward depends upon the shape of the two portions of the separated lip. It is unnecessary at the beginning of the operation to estimate the length correctly, as the incision can be prolonged later on, after some of the sutures have been applied and tied, according to the requirements of the shape of the lip when united.

2. *Sutures of the Prolabium.*—Interrupted

sutures of fine silk are applied or inserted from the mucous surface so as to place the knot of the suture in the mouth, the first suture close to the top of the triangle as shown in Figure 2. The ends of the sutures are left long and held together with an artery forceps which is left hanging down. The succeeding sutures are applied in a similar manner at a distance of from three to five millimeters from each other in a number corresponding to the extent of the line of prolabium to be united. These prolabial sutures should include the mucous membrane and sub-mucous tissue only, or as little tissue as will suffice to keep the prolabial edges together. There must be no tension whatever at the line of union; if tension exists from shortness of the labial flaps, it must be overcome by the tension sutures, which will be described later.

Figure 1.

Figure 2.

When apparently a sufficient number of these sutures have been applied, they are tied from above downward, or from the nose to the prolabium, the upper or nasal suture first, the forceps being held up toward the forehead. The united line must be long enough to give sufficient length to the lip, and permit the lowest point of union to be a little lower down (toward the lower lip), than the sides of the lip and the corners of the mouth. The wound to be united is now closed against the mouth—is made a sub-cutaneous wound.

Sutures of the Skin.—1. Tension Sutures. According to the size of the defect, one or two tension sutures become necessary. I have entirely discarded the figure-of-eight suture with harelip pins, and also the button and shot sutures, and always employ an interrupted suture, using silk a little heavier than that used for the coaptation sutures of the prolabium and skin. In ordinary cases of single harelip one tension suture is sufficient. This suture enters the skin at a distance of one quarter to half an inch from the cutaneous margin of the wound, and is passed deeply down into the tissue of the lip. Care is taken not to have it pass through to the mouth,

but to have it take in about two-thirds of the tissue of the lip as shown in Figure 4 a. This tension suture should be placed at or near a point where the margins of the wound are the greatest distance from each other—that is, near to the prolabium of the undivided portion of the lip. The tension suture is left with long ends held by artery forceps, and should not be tied until all the cutaneous coaptation sutures have been inserted.

Figure 3.

2. Coaptation Sutures. These sutures (Figure 4, b.b.b.), for which common silk twist (which may be bought in a dry goods store, and disinfected in the usual manner by boiling it from fifteen to thirty minutes in a 5 per cent. solution of carbolic acid) is used, are applied from above downward, or from the nasal angle of the wound to the prolabium, at a distance of three to five millimeters. Three to five sutures are usually required. The lowest suture (Figure 4, c.), is passed through the ununited borders of the prolabium.

The wound is now carefully cleansed by small aseptic sponges, and is finally touched with a sponge wrung out from 2½ per cent. of carbolic acid, or a 1 to 2,000 sublimate solution.

If any hæmorrhage is present it can be stopped by continued pressure with an aseptic sponge for a few minutes; if the hæmorrhage is slight it will cease upon tying the sutures.

The closure of the sutures should begin with the tension suture, so as to prevent the coaptation sutures from tearing through, as they would be liable to do if tied before all tension was done away with.

If in drawing the sutures together it is found that the middle of the lip does not come down low enough, or that there is still an indentation in the prolabium at the line of incision, it is advisable to prolong the cutaneo-prolabial incision a little on one or both sides, as the shape of the lip may require, and then apply an additional cutaneous coaptation suture.

Figure 4.

When the cutaneous sutures are tied, the united wound should present the appearance shown in Figure 5.

4. *Dressing of the Wound.*—After careful cleansing of the line of the wound with saturated solution of boracic acid, a layer of finely powdered boracic acid is dusted on, and a cotton-collodion dressing applied. When I began to use this method I plugged the nostril with borated cotton, but on account of its inconvenience to the patient, have now discontinued this practice. I do not use iodoform-cotton or iodoform-collodion dressing for fear of iodoform poisoning; I prefer to have the nurse or mother dust finely powdered boracic acid into the nostril every three or four hours during the day.

A single or double strip of rubber adhesive plaster, extending from ear to ear, is applied over the collodion dressing in such a manner as to draw the two cheeks somewhat together, for the

purpose of immobilizing the cheeks and lips when the child cries or nurses.

The dressing may be changed once a day, or every two or three days if it remains dry. If, however, the dressing becomes soaked by nasal secretion, or milk when the child is nursed, it should be changed according to the necessity of the individual case.

Figure 5.

5. *Removal of Sutures.*—The cutaneous coaptation sutures are removed after a week; the tension suture is allowed to remain two to four days longer if it has not been loosened by pressure atrophy, or pressure necrosis of its canal. After removal of the sutures, the borated cotton-collodion dressing and adhesive straps are re-applied to be continued until the suture canals have entirely healed, which takes place toward the end of the second or third week.

Figure 6.

Figure 7.

At the junction of the two lateral corners of the wound there often remains after the suturing a small quadrangular ununited space one to two millimeters in diameter, where it may have been impossible to approximate the edges of the wound. (Figure 5 a.). A very fine suture may help to close this little defect. If, as is often the case, this little suture cuts through, the small defect heals by aseptic granulation, requiring only very little more time than the primary union of the remainder of the wound. It leaves at most a small cicatrix in the line of union at the border of the skin and prolabium, and does not result in permanent disfigurement.

The prolabial sutures will sometimes cut through and peel off if the process of healing goes on undisturbed, or some of the sutures may remain and be removed after the end of the second or third week, at a time when union is strong enough to tolerate the manipulations necessary for their removal.

II. OPERATION FOR DOUBLE AND COMPLICATED HARELIP.

The operation for double and complicated harelip (as represented in Figures 6 to 9), is performed on the same general principles, namely:

1. *Incision.*—The incision along the cutaneo-prolabial border should be of sufficient length to cover the space of defect. A second incision should be made along the cutaneo-prolabial border of the median peninsula of labial tissue below nasal septum, if this peninsula is so situated as to be available for use in the formation of the lip. (See Figure 6).

Figure 8.

2. *Suture of the Prolabium.*—The prolabial sutures are applied as just described for the unilateral harelip, to be tied on the oral surface of the wound. The sutures should be first inserted on both sides of the nasal peninsula until this is wholly covered, and until both lateral halves of the prolabium come together at the median point of its lower border. (Figure 7, a.). When this point is reached these two rows of sutures are tied.

The lateral prolabial borders are now united in the median line as low down or as far out as required to give to the lip the necessary length, as described in the operation for single harelip. These labial sutures are tied in the mouth usually without any tension, because the prolabium when loosened from the skin and retracted, furnishes a flap of sufficient size and elasticity to permit of ready approximation.

It is important, as before stated, that the linear

incision should not penetrate into the mouth. When, as is often the case when the cleft extends through the nostril or nasal cavity, there is a lack of prolabium near to and in the nostril, and the prolabial sutures cannot be applied high up, it is usually possible, by careful dissection and separation of the mucous membrane at the oral fornix of the lateral half of the upper lip, to displace the mucous membrane to some extent laterally, so that the uppermost suture may be applied reasonably high up toward the nostril.

When the prolabial sutures have been tied the wound presents the appearance represented in Figure 7.

3. *Sutures of the Skin.*—Tension and coaptation sutures are now applied as follows: (See Figure 8).

1. *Tension Sutures.*—For these sutures somewhat heavier silk should be employed. The upper suture should be inserted at the lower border of the nasal peninsula, the lower one near

Figure 9.

the lower border of the lip. They should be passed in and out at a distance of a quarter to half an inch of the border of the skin, and should include one-half or a little more than one-half of the thickness of the lip. (Figure 8, a.) The ends should be held by artery forceps, and should not be tied until all the skin sutures have been applied.

2. *Coaptation Sutures.*—The coaptation sutures (Figure 8, b. c.), are now inserted from above downward. The first two or three sutures (Figure 8, b.), are inserted on both sides between the lateral skin flap and the skin of the peninsula, until this is united to the side flap throughout its entire circumference. The lateral flaps, uniting in the median line just below the nasal peninsula, forms the upper portion of a Y-

shaped line of union. Then the lower portion of the wound is united by two or three sutures (Figure 8, c.), and a lower fourth suture (Figure 8, d.) is inserted through the two halves of the prolabium.

After thorough cleansing and disinfection of the wound, the sutures should be tied: first, the tension, and then the coaptation sutures (Figure 7).

4. *Dressing of the Wound.*—The wound should be dressed with borated cotton-collodion, or in older patients, with iodoform collodion. The nostrils, especially in older patients, should be loosely packed with borated or iodoform cotton. Over this two straps of adhesive plaster should be applied. In older patients a strip of iodoform gauze should be laid in the mouth along the line of union of the prolabium. In new-born children the nostrils need not be packed with cotton, and no iodoform gauze should be used; but these localities should be frequently dusted with finely powdered boracic acid. The dressing should be changed according to the amount of discharge, never more than once daily.

5. *Removal of Sutures.*—The coaptation sutures of the skin may be removed at the end of the first week; the tension sutures, according to the amount of tension remaining, usually late in the second week; finally, what may remain of the prolabial sutures should be removed still later, when the union is so solid that the upper lip is able to tolerate manipulation.

It is immaterial how narrow the new upper lip may appear to be immediately after the operation. König remarks (in speaking on plastic operations on the lips—keiloplastic operations following the extirpation of labial carcinomas), that the shape of the mouth, however deformed it may appear, on account of unequal size of the lower and upper lip in the first weeks after the operation, that in the course of some months the shape of the oral orifice and lips becomes more normal, surprisingly so when a sufficient time, from three to six months, has elapsed.

The all-important feature of the operation is to make the upper lip long enough in a sagittal direction, and to have exact union of the lower portion of the prolabium.

Apparatus to draw the cheeks together for the sake of immobilization or to diminish tension, I have, up to this time, found superfluous.

CONCLUSIONS.

The two main points in this harelip operation are the incision and the prolabial sutures.

1. The incision, a linear incision, is similar to that made in the operation for laceration of the perineum as proposed by Lawson Tait, and by him termed "flap-splitting." As stated above, this possesses the advantage of not sacrificing any tissue of the parts already more or less de-

fective; on the other hand, repeated denudations made necessary by unsuccessful attempts at union would tend to make the lateral portions of the lip smaller and smaller. Furthermore, the linear incision, by loosening the everted prolabium (which is readily converted into mucous membrane by the simple change of position into the oral cavity), furnishes so much tissue for the posterior surface of the lip that union of the prolabial borders is easy, even before any tension sutures have been applied.

2. The prolabial sutures should be accurately applied. Fine curved needles should be used, the sutures made of fine silk. Interrupted sutures should be employed, in sufficient number and at sufficient intervals to furnish exact union. These sutures close the wound against the mouth and make the wound, so to speak, cutaneous instead of visceral, and thereby prevent infection from the ever-present multitude of microbes in the mouth. I believe that this suture will prove to be a potent factor in securing uniform results by preventing suppuration and non-union of the wound.

3. The cosmetic results have been all I could desire. If a slight indentation at the line of union of the prolabium has existed immediately after the operation, it has generally disappeared after a few months, provided the lip has been made long enough at the time of the operation.

4. I think that this method is applicable in all cases, and should take the place of all the numerous older methods of operating.

SPRAINS OF THE ANKLE.

Read in the Section of Surgery and Anatomy, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY W. R. TOWNSEND, A.M., M.D.,
OF NEW YORK.

ASSISTANT SURGEON, HOSPITAL FOR RUPTURED AND CRIPPLED; ORTHOPEDIC SURGEON, NEW YORK INFANT ASYLUM; LECTURER ON ORTHOPEDIC SURGERY, NEW YORK POLYCLINIC.

There is a popular impression among many of the laity "that a sprain is worse than a fracture," yet, to judge from the amount of space devoted to the subject in our text-books on surgery, it is evident that their authors do not agree with the statement. We must, however, admit that some grounds exist for the belief, and that, while we seldom hear of an ununited fracture, or of a fracture causing trouble years after the original injury, we are constantly meeting with cases of chronic sprain of the ankle, of flat foot, of various forms of bone and joint disease which we can clearly trace to a sprain. Several reasons exist for this state of affairs, and in many instances, the reason may be clearly shown to be the faulty or neglected treatment of the original injury.

Mr. Mansell Moullin, of London, in his most thorough and interesting monograph on "Sprains;

their Consequences and Treatment," says in his Introduction: "Few injuries are treated with so little consideration as sprains. It is impossible to overlook wounds, owing to the bleeding and pain which accompany them. Fractures, it is understood, require rest and care; but sprains, in which the tissues are torn to such a degree that the damage is far more serious than in many fractures, merely because they are so common, are considered of little or no consequence. It counts for nothing that the part injured is one of the most complicated structures in the body, and particularly liable to inflammation from the constant use to which it is subjected. Yet a fracture is regarded as very serious, a sprained joint as quite a trivial matter." Other authorities could be quoted to show that sprains in many cases receive little or no treatment; the patient is dismissed with the statement that it is only a sprain; bathe it in hot or cold water, or rub a little arnica or Pond's extract on your ankle. Nothing more is thought of the case, and years afterwards, the original injury having almost been forgotten, the sufferer applies to some specialist for treatment.

This state of affairs is very graphically described by Royal Whitman, M.D., in an article read before the American Orthopædic Association in 1890, on "The Treatment of Persistent Abduction of the Foot, commonly known as Chronic Sprain of the Ankle." He says: "The successful treatment of any chronic affection demands a personal, persistent attention to details on the part of the surgeon. This is particularly true of the treatment of what are known as minor injuries, and therefore neglected. One of this class, commonly known as chronic sprain of the ankle, may entail years of discomfort and disability, with permanent impairment of the functions of the foot. The usual history of such cases is as follows: Long-continued weakness and discomfort, following an injury to the ankle, treated by various physicians with liniments, blisters and bandages, until the discouraged patient is told that nothing more can be done, but that his symptoms 'will wear away in time.' A year or two later he presents himself, usually for the purpose of securing a brace, or for some peculiar shoe which he thinks may be of service to him."

I have quoted thus at length, because it is my firm belief that most of these disagreeable after-effects can be avoided, if the patient and surgeon will simply recognize the fact that every sprain, no matter how trivial, is worthy of treatment.

The prevention of a flat foot is easier and more satisfactory than its treatment, and a large number of the cases have their origin in a simple and neglected sprain of the ankle. The same is true of bone lesions, and if the injury is recognized, and its importance admitted, many cases will

thus be saved from the unpleasant symptoms, so common, as the result of the practice of considering sprains as slight and unimportant injuries.

The definition of a sprain as given by Webster—the weakening of the motive power of a part by sudden and excessive exertion—describes both the manner of production of the injury and the result produced, but a more accurate and better definition is that given by Mr. Edward Cotterell, in his little book on "Some Common Injuries to Limbs." He says: A sprain includes all injuries to a joint and its surrounding structures produced by a sudden twist, but stopping short of dislocation.

Many degrees of severity may exist, and the classification adopted by S. L. McCurdy, M.D., in an article on "Sprains and their Treatment," which appeared in the *Columbus Med. Journal* for January, 1891, is a very good one.

He divides them into three classes. In the first there is simply a contusion of synovial membrane and a stretching of the soft parts; in the second there is a rupture of the ligaments and synovial sac; and in the third "sprain fracture"—the ligament, instead of tearing, pulls off a thin layer or slice of bone. This accident, though infrequent, perhaps might best be considered under the head of fractures.

A better method of studying the cases, seems to me to be that adopted by Mr. Moullin in the monograph previously alluded to, and its perusal will repay those interested in the subject.

He discusses the effect produced on each tissue by such injuries, and the mutual sympathy of all the parts. The ankle-joint is particularly liable to sprains, its normal movements being flexion and extension, in alighting upon uneven surfaces, whether from a height or from some moving body, as a car, wagon, etc., unless the foot is evenly placed, the weight of the body being suddenly thrown on the joint, causes the foot beneath it to twist, and a violent wrench or sprain ensues. Severe pain is felt, in most cases limited to the parts near the ankle, in other cases extending up the limb. In the most severe cases, a condition of shock may even result, and the entire nervous system apparently becomes deranged.

Moullin says: The pain when ligaments are torn is usually described as sickening in character, and those who have once felt it, rarely fail to recognize it a second time. If a muscle is strained, there is generally a peculiar sensitiveness of the skin, most marked over its points of attachment to the bones or tendons. Slight touching of the part may cause exquisite pain, yet firm pressure may be well borne.

When the muscle is torn across, either partially or wholly, there is a sharp pain, like that of a blow with a whip or a cricket ball, so that the patient may turn around to see who has struck him before he is aware anything has given way;

and then, as the swelling begins, this is followed by a feeling of stiffness and soreness, severe even when the limb is at rest, but so much worse when an attempt is made to use it, that the patient can often hardly be induced to try. Similar pain occurs when a muscle is dislocated, and after the restoration there remains a sensation of soreness, with a tender spot corresponding to the slip displaced. These tender spots may remain for a long time in the ankle, if a lateral ligament has been torn away from the bone—but allowance must be made for those that are normally present when a joint is hurt. What they are caused by is not always certain, but as a rule they correspond to points where the capsule is thin and flexible and not far removed from the surface, so that pressure falls directly on it. At the ankle there is generally one on the front of the joint, rather to the outer side of the middle line.

Swelling more or less severe follows. The joint may become distended with synovial fluid, or blood may become extravasated into it. The appearance of the swelling may be very rapid, in many cases extreme, and followed by inflammatory symptoms—increased local temperature and redness, later on perhaps followed by an increase of the body temperature, if the inflammation be very severe. Motion of the affected joint may be slightly diminished, or even entirely lost, spasm of the muscles in proximity to it occur, and motion is thus limited, or the patient may voluntarily contract the muscles, from fear of being hurt, and thus produce spasm. Staining occurs at or near the site of injury, due to the extravasated blood, the color varying according to amount extravasated and the time it is seen after the infliction of the traumatism. If the bursa is injured, a teno synovitis or bursitis may follow, characterized by the presence of fluid in the bursal sac, and in some cases, later on, by adhesions. The close resemblance of these sprains to many dislocations is clear when we recognize, as was done by Vidal de Cassis, that they are really the same thing, only that reduction has taken place spontaneously.

Having thus briefly considered the pathology and symptoms, the question of treatment should not be a difficult one.

If we recall the anatomy of the ankle, we find that it is superficial, not covered with much fatty or muscular tissue, surrounded by ligaments and tendons, and that the latter have reflections of the synovial-like membranes from their sheaths, forming bursæ. The indications are to give the injured parts support and rest, restore the joint functions and prevent inflammation.

It is of course understood that a careful differential diagnosis must be made. The sooner the case is examined after the injury the better. Fractures and partial dislocations, bone or joint disease, must be carefully excluded.

If any doubt exist, give the patient the benefit of that doubt. Do not hesitate to give an anæsthetic if, for any reason, careful and satisfactory examination cannot be made without it. This is of great importance from a medical as well as a legal standpoint, as a case of Pott's fracture or fracture of tibia, fibula or tarsal bones, if treated as a sprained ankle, might cause serious trouble. These mistakes should and can be avoided. When the lesion has become chronic, the diagnosis is often difficult, and bone disease is easily mistaken for chronic sprain of the ankle, but we are supposed to be dealing with the acute or recent cases. How best to fulfil the indications of treatment depends somewhat on the individual case and the facilities at hand. Rest of the part with preservation of its function, seems to me best accomplished by means of a dressing of adhesive plaster which I call the Cotterell dressing, as Mr. Cotterell was the first to use it in sprains of the ankle, although the idea was suggested to him by Mr. Wharton Hood (*Lancet*, Vol. ii, 1884, p. 728), for the treatment of what is known as lawn tennis leg. The limb is elevated, to assist in reducing the swelling, then strips of adhesive plaster, each $1\frac{1}{2}$ inch in width, and of the length adapted to the foot and ankle joint, are applied, somewhat as strapping is applied in the treatment of chronic ulcers of the leg. It is not advisable to use strips narrower than one inch, as they may cut the parts by a curling up of edge of the plaster. Over this a firm roller bandage is applied, and the patient is directed to get up and walk. The adhesive plaster causes a firm and even compression of the parts, acts as a light splint, prevents exudation and permits motion, which in the mild cases is desirable. The patient may come into the office limping and heavily leaning on a cane, and yet after the application of this dressing, if he is once persuaded that motion will not injure his joint, he is enabled to dispense with the cane, and in a short time walk with comfort. In one case a policeman weighing 280 lbs., although he had not stepped on his foot for three days after a severe sprain of the ankle, was enabled to return to duty within six hours after its application. This treatment is recommended where the injury simply consists in a wrenching of tissue and a contusion of synovial membrane.

In the more severe injuries, when ligaments are torn across, muscles ruptured, synovitis or bursitis present, the parts should be strapped, and then foot and ankle encased in a plaster of Paris or silicate of soda splint. Care should be taken that the foot be put up at a right angle with the leg, and in a position of varus, not of valgus. The strapping in all cases should be renewed in a few days, as, when the swelling subsides, it becomes loose. The plaster of Paris must not be left on too long, as when acute symptoms subside motion is desirable, to prevent adhesions

and stiffness of the joint. If extreme swelling or inflammation have occurred before case is seen, then heat, cold, the various antiphlogistics, may be used, and after these massage and electricity. Support is needed as long as there is swelling or marked tenderness.

It is not intended in this paper to discuss the subject exhaustively, but rather to call attention to the fact that sprains of the ankle, even of slight degree, are worthy of careful treatment, and that, in my opinion, the Cotterell dressing is the best form of treatment in the mild cases, and the Cotterell dressing and plaster of Paris in the more severe.

THE RELATION OF CALCULI TO MALIGNANT DISEASE OF THE LIVER AND KIDNEYS.

Read in the Section of Surgery and Anatomy, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 5-8, 1891.

BY I. S. STONE, M.D.,

SURGEON TO COLUMBIA HOSPITAL, ETC. WASHINGTON, D. C.

Since it has become the established surgical method to explore the abdomen in case of doubtful diagnosis, we have definite scientific knowledge, which can often be used for the well-being and safety of the patient while alive, instead of merely adding to our stock of post mortem information. Among other beneficent results to which we have fallen heir is the improved surgery of the liver and kidneys. In the performance of these operations, many surgeons have noted the frequency of the correlation of biliary and renal concretions with malignant disease. The following case will illustrate the subject to which I desire to direct attention in the present paper.

Mrs. —, age 65, had from time to time for six months before my attention was called to the case, attacks of biliary colic. Her physician had given the usual treatment, such as olive oil, etc., with the alleged result of causing the evacuation of several "rather soft" gall-stones. (I have never had any reason to think olive oil any better drug than any other substance capable of being saponified, or otherwise causing fatty or soapy masses to pass per anum resembling gall-stones).

At last, after much delay, and the advent of grave symptoms of collapse, the patient was referred to me for operation. There was slight jaundice, the urine highly colored with bile, and the usual stools seen where there is absence or deficiency.

There was some enlargement of the liver just over the gall-bladder, and some emaciation of the patient. Diagnosis, gall-stones, with probable malignant disease. The operation was a very simple one. As soon as the peritoneum was opened, and before a sponge could be securely placed in position, an abscess opened and poured

out two or three ounces of offensive pus. The malignancy was beyond doubt, and quite a number of gall-stones were quickly removed, although no time was lost in searching for them. The peritoneum was stitched to the abscess wall, thus securing the peritoneal cavity from infection for the time, and a drainage tube and dressing completed the operation. The patient was quite comfortable after the operation, not even requiring morphia, as she had done previously. She lived very comfortably for three weeks, and died of uncontrollable hæmorrhage from a vessel deeply seated in the liver. This case, and several autopsies where a similar condition was found, have led the writer to a study of these phenomena, and the points at issue are these:

Are calculi a cause of malignant disease, or are they a result?

Is their presence merely a coincidence?

Or are calculi very often present without giving rise to symptoms, or disease, and only found post-mortem?

It is quite possible that vague and indefinable symptoms, very often reflex in their manifestations, leave us in doubt as to their significance.

That there is an element of truth in all these statements is beyond question. It has been shown by several authorities that the kidney is not so frequently invaded by malignancy as a result of calculous disease as is the liver. For instance, Ralfe gives "renal calculi" a cause of cancer, as we often find renal concretions in cancerous kidney, though it is certainly not such a frequent clinical sequel as is the case in biliary disease.

A clinical instance is given by Dr. Norman Moore (*London Path. Soc. Rept.*, 1882); also an instance by Mr. Pollard in same *Trans.* for 1885 (*Ralfe, Dis. of Kidney*).

In St. Bartholomew Repts. we find, Vol. XXI, a case reported of nephrolithotomy for calculous pyelitis, and after death not only an abscess, but epithelioma, was found, which was produced by the irritation of the calculus (*Newman, Surg. Dis. Kidney*).

The writer has notes of one case of chronic Bright's disease in which, at the autopsy, several calculi were found in one kidney. No positive symptoms of stone were recognized during the patient's life.

Dr. Bright early recognized the coexistence of renal calculus and cancerous disease. One report shows the finding of a lactic acid formation in one kidney, and an oxalic stone in the other.

Another case mentioned by Brodeur (*p. 170, Newman's Dis. Kidney*): A female, æt. 36. R. Kidney tumor removed by abdominal method. "Patient died in two days. Weight of tumor, 1 lb. Pelvis and calicis contained calculi, although the microscopist said the disease began in the epithelial lining of the renal tubules."

Epithelioma appears to most frequently follow this form of irritation ; at least, more frequently than other forms of cancer.

If evidence is given that the kidney is probably the seat of cancer as a result of calculous irritation, we are abundantly able to show that the liver is much oftener attacked by malignant disease than these organs. In Guy's Hospital Reports for 1875, Dr. Hilton Fagge reports forty-two autopsies, covering a space of fifteen years, showing an intimate correlation of calculi and carcinoma. He says: "But the way in which death is most frequently brought about in persons who have gall-stones is by the development of cancer about the gall bladder or the bile ducts. Within the period of twenty-one years already referred to there have been at least twelve cases in which gall-stones being present, there has been likewise malignant disease of these structures. In some instances, the clinical history has pointed distinctly to the view that the jaundice was originally due to an ordinary attack of biliary colic, and that the development of cancer was secondary. Indeed, one case seems to admit of no other interpretation. (The case is given at length.) But in the great majority of cases in question, no gall-stone has been impacted in the duct at the seat of the cancer. The concretions have been found in the gall-bladder itself, which has often contracted round them, and empty, or containing only a little purulent mucus. Thus it appears probable that if the malignant growth had not developed, all the symptoms would have subsided, and the health of the patient would have been restored. All observers, indeed, are not agreed that the cancer of the bile-ducts arises secondarily when it is found in association with gall stones. It has been urged that the gall-stones are often discovered in the bodies of those who have died from cancer of the breast or of other organs. This may be merely a coincidence, for both cancer and gall-stones are especially apt to occur in persons advanced in life. However, even if some deeper relation than at first sight appears probable should be proved to exist between the formation of biliary calculi and the development of cancer in the body generally, this would not do away with the clinical significance of the facts stated above ; it would still remain true that when a patient who has had attacks of biliary colic dies of protracted jaundice, the ducts are almost invariably found to be affected with cancer." . . . "Statistics show the jaundice as a symptom of cancer is just twice as frequent as owing to gall-stones." Dr. Markham (*Harley, Dis. Liver*) reports a case which was supposed to have been pyloric disease. Patient, age 28. Intense jaundice ; pain ; vomiting after eating ; urine deeply colored with bile ; no bile in stools. At autopsy the gall-bladder was found converted into a large and solid mass of scirrhus, which

commenced in the coats of the viscus itself. In the center of the mass was found a number of gall-stones, which were supposed to have to do with the formation of the cancerous deposit.

Dr. Coupland (*Trans. Path. Soc., Lond.*) reports another case in a woman, æt 56. A large number of calculi were found in the center of a malignant tumor. Dr. Harley mentions another case reported by Dr. Norman Moore, occurring in a woman aged 59. One case appears to have been attributed to the operation of gastroenterotomy.

Harley says (*Dis. Liver*) : The liver and gall-bladder are alike subject to irritation and cancer resulting from gall stones. Gall-stones apparently, indeed, not only give rise to serious organic changes in the wall of the viscus, such as inflammatory thickening, and hypertrophies, but to the formation of new growths in the shape of benign, scirrhus and malignant encephaloid tumors. After mentioning a case of acute yellow atrophy of the liver, associated with biliary calculi, Murchison says, p. 271, ed. 1877 : "It is remarkable that most of these cases (alluding to secondary cancer of the bladder from extension of the disease from liver and pancreas, more commonly commencing in the gall-bladder, and secondarily affecting the liver and peritoneum), the gall-bladder contains calculi, and the cancer appears to be the sequel of gall-stones. Not infrequently there is a history of biliary colic. (P. 372). The passage of a gall-stone, with or without hæmorrhage from the bowels, concurring with a tumor, would corroborate rather than refute the diagnosis of cancer." Murchison gives histories of cases in support of this opinion. These cases support the view announced by Dr. Fagge, "that there is frequently a history of biliary colic preceding the onset of cancer."

Authorities differ greatly upon the question of the relation of carcinoma to gall-stone formation. Until recently, most observers were inclined to look upon the cancer, or the cancerous diathesis, as the cause rather than the effect of the calculi. Several recent clinical observations would appear to confirm the belief that calculi may be the irritating cause in some cases. Quetsch (p. 39) relates the history of a female patient who had a biliary fistula opening upon the surface, the result of a long-standing calculous disease. Some of the calculi did not pass through the fistula, and carcinoma of the gall-bladder, which developed, was attributed to the irritation produced by their presence in the organ. The article in *Buck's Ref. Hand-book Med. Sci.* clearly favors the above view. Frerichs notes the coincidence of cancer of the biliary system and calculi, having, in eleven cases, found calculi nine times. This subject has claimed some attention from clinicians and pathologists for many years, but there are few, if any, authors who have attempted

to collect a résumé of the literature of the subject.

Dr. Arthur Willigh (*Virchow's Arch.*, 1869) reports one case. A writer in the *Bulletino delle Scienze Mediche di Bologna*, 1871, adds his voice in favor of the above views, and gives a case occurring in a woman aged 48. Dr. Kraus, of Carlsbad, mentions a case of primary cancer of ductus cholodochus produced by the wedging of several stones in the canal. (*Prag. Med. Woch.*, 1875.) Dr. Harley mentions one reported by Dr. Vanderbye. (*Path. Soc. Trans.*, 1858.) A woman, age 64, having extreme liver disease of malignant character, with neither jaundice nor anasarca, and with forty gall-stones in her gall-bladder.

The fixed idea that injuries of the liver may cause the development of cancer, if true, gives color to the possibility of cancer being caused by calculi. Harley strongly presents this view, that either injury or irritation of the nerves or tissue of the liver is a far more frequent cause of its malignant degeneration than the majority of physicians suppose. Just here I would mention that, as it is generally supposed that jaundice is nearly always present in malignant disease of the liver, statistics seem to show that in only a small proportion of all cases is it present save in last stages of the disease. It is also further worthy of remark that many cases of gall-stone are present with jaundice without cancer in proportion of two to one. Among American writers I find but little said upon this subject. Dr. Ransdorf and Dr. Musser, of Philadelphia, are exceptions; both indorse the views of authorities quoted in this paper. In closing, I do not think it important to comment upon the remaining phases of the question as to the cause of cancer, as, for instance, the cachexia of cancer favoring the formation of gall-stones. The study of reported cases shows plainly the deposit of cancer formation as a result of mechanical irritation, of which there are instances in other parts of the body. We have not lost sight, however, of the possibility of cancerous obstruction adding to the possibility of calculous formation, although we incline to the idea that the slow formation of calculi must date far beyond the period when the fatal obstruction from cancerous deposit occurs.

(Note.—Since the meeting of the Association, the following notes have been prepared, to be added as a postscript):

W. H. Larmond, in *Le Prog. Medical*, 387, 1882, reports a case of biliary calculus, grave icterus, and cancer of the liver. Patient's age, 75. Several calculi size of filberts.

H. Zenker, *Deut. Arch. f. Klin. Med.*, Band xiv., says of the method of transformation to cancer: "The malignant process in these cases starts in much the same manner as does a cancer of the stomach from the edges of a benign ulcer."

Zenker was able to find, on microscopic examination, that cicatrices of the gall-bladder, caused by the presence of gall-stones, were accompanied by an outgrowth of epithelium not only from the gall-bladder, but in the adherent parts, such as the transverse colon, or the common bile-duct. Where the points of transmission lie between such a typical epithelial growth and the commencement of actual cancer it is not possible to say. The author holds that the passage from one to the other is gradual, and that old age is a predisposing cause.

In *Trans. Med. Soc., Lond.*, vol. xli., 1889-90, p. 40, Dr. H. Handford communicates an interesting history of a female patient, age 55, who had cancer of the portal fissure of the liver, jaundice, impacted gall stones, combined with interstitial hepatitis (atrophic cirrhosis). Very many gall-stones were found in this case. The points of special interest were these:

1. The association of carcinoma with impacted gall-stones. The author well says: "This is not very rare, although not so common as the association with non-impacted stones."

2. The presence of multiple strictures of the intestine. Neither excision of the rectum or inguinal colotomy would have given much relief in this case, because of the obstruction higher up.

3. The association in the liver of interstitial hepatitis with disseminated carcinoma.

1309 H street, N. W.

SUPRA-PUBIC CYSTOTOMY.

Read in the Section of Surgery and Anatomy at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY JOHN A. WYETH, M.D.,
OF NEW YORK.

The personal experience upon which this report is based embraces twenty-three operations, in all of which recovery ensued. They may be, for purposes of study, divided into:

1. Tumor of the bladder 6 cases.
2. Tumor of the bladder, with stone 2 "
3. Stone (without tumor) 3 "
4. Foreign body 1 case.
5. Cystitis, without tumor, stone or foreign body (one case with fistula) 11 cases.

23 cases.

I. TUMORS.

Case 1.—Male, aged 40. Operation July 7, 1888. Seven months before, hæmaturia, chills and fever. Diagnosis, cancer of bladder. Large epithelioma removed. Drainage tube removed eighth day. Urine ceased to escape through wound on sixteenth day. Recovery. Improved. Six months later, death from general metastasis and exhaustion.

Case 2.—Male, 36 years old. Operation July

20, 1888. Small benign sessile tumor removed from floor of trigonum. Drainage tube removed sixth day. Wound closed on eighteenth day. Recovered. Cured.

Case 3.—Female, 20 years old. Small, pedunculated, benign tumor at commencement of urethra, forming ball-valve, and stopping free outflow of urine. Operation March 26, 1889. Wound in bladder closed at once. Catheter per urethram ten days. No leakage. Recovery.

Case 4.—Male, 54 years. Operation October, 1889. Tumor of bladder just behind urethral opening removed (third lobe of prostate). Drainage for eight days, and wound closed. Recovery.

Case 5.—Female, 42 years. Operation December, 1889. Valve like fold of hypertrophied or thickened mucous membrane partially closing outlet of bladder. Removed. Wound in bladder closed at once by suture. Recovery. Cured.

Case 6.—Male, 62 years. General hypertrophy of prostate, enlargement of middle and both lateral lobes, chronic cystitis for three years, and with partial paralysis of bladder from over-distension. Operation November 12, 1890. Recovered, much improved. Permanent drainage necessarily established.

2. TUMORS COMPLICATED WITH CALCULUS.

Case 1.—Male, 67 years. Operation September 4, 1888. Tumor of prostate and calculus removed. Tube removed sixth day. Wound closed by sixteenth day. Recovery. Cured.

Case 2.—Male, 48 years. Operation September, 1889. Tumor and calculus removed. Drainage for about ten days. Recovery. Cured.

3. STONE UNCOMPLICATED EXCEPT WITH USUAL CYSTITIS.

Case 1.—Male, 46 years. Operation September 28, 1888. Large stone removed. Tube discontinued eighth day. Fistula persisted for four weeks. Scraped this out and it then closed. Recovery. Cured.

Case 2.—Male, 60 years. Operation December, 1889. Piece of catheter four inches long, thickly incrustated with urine salts, removed. Tube discontinued fifth day. Recovery. Cure.

Case 3.—Male, 16 years. Operation March 9, 1890. Oxalate of lime stone about one inch and a half in diameter removed. Drainage five days. Wound closed on fifteenth day. Recovery. Cure.

4. FOREIGN BODY (UNCOMPLICATED).

Case 1.—Male, 41 years. Operation July 25, 1888. Piece of metal catheter removed. Tube discontinued fifth day. Wound closed fourteenth day after operation. Recovery. In this case, immediate suture would have been permissible.

5. CHRONIC CYSTITIS WITHOUT TUMOR OR STONE.

Case 1.—Male, 40 years. Operation Decem-

ber, 1888. Drained three weeks. Wound closed gradually. Recovery.

Case 2.—Male, 68 years. Old persisting fistula from former operation with cystitis. Fistula opened up; scraped out; wound allowed to close. Recovery.

Case 3.—Male, 54 years. Cystitis after previous operation. Usual drainage. Recovery.

Case 4.—Male, 4 years. Cystitis, with paralysis due to compression of cord. Tube removed fourteenth day. Wound closed gradually. Recovery.

Case 5.—Same patient. Drainage reëstablished by operation, and prolonged. I opened the spinal cord, evacuated abscess of the cord, and cured the paralysis in this case. Recovery.

Case 6.—Male, 24 years. Cystitis for eighteen months. Operation March 14, 1890. Drainage three weeks. Recovery.

Case 7.—Male, 36 years. Cystitis for one year. Operation March 28, 1890. Drainage two weeks. Wound closed in four weeks. Recovery.

Case 8.—Male, 58 years. Impermeable stricture of urethra and cystitis. Drainage for six weeks. Patient had cerebral hæmorrhage, and died eight weeks after the operation from compression of brain. Cystitis was cured at time of death.

Case 9.—Male, about 45 years. Complete paralysis of bladder, and cystitis. Permanent drainage. Recovery.

Case 10.—Male, 59 years. Chronic cystitis and neuralgia of the vesical neck and prostate. Operation January 28, 1891. Drainage tube removed fourteenth day. Small area of thickened mucous membrane over trigonum removed. Wound closed gradually. Cystitis relieved. Neuralgia not benefited, and patient, May 5, 1891, at home, but still a sufferer from prostatic neuralgia.

Case 11.—Male, 63 years. Operation March 9, 1891. Tube removed fourteenth day. Wound about closed April 22, when patient was last seen. Recovery.

The operative technique is as follows:

The preparatory treatment consists in emptying the alimentary canal by laxatives and enema. The pubes and perineum should be shaved before the anaesthetic is given. After narcosis is complete, the patient should be placed on the back, the pelvis about six inches higher than the head, so that the contents of the abdomen may gravitate toward the diaphragm. A soft catheter is inserted, and the bladder filled with eight or ten ounces of warm Thiersch's solution, which is allowed to flow out through the catheter, and this is repeated until the fluid escapes fresh and clear. Finally, about ten ounces of this solution are injected, the catheter withdrawn, and the urethra closed by ligation of the penis with rub-

ber tubing. In females the bladder is kept full by digital pressure of the urethra against the arch of the pubis, or by plugging.

In cutting into the bladder, the point to be made for is the upper surface of the symphysis pubis. The incision usually extends about two inches above and an inch below this point. In very fat subjects it may be more extensive. It should be exactly in the median line, through the skin and muscles. It is usually an advantage to snip the muscles from the upper margin of the pubic bones for a half inch on either side. In case a large tumor or stone is encountered, this lateral incision may be enlarged to within one-half inch of the inner pillar of the external abdominal ring. The supporting power of the muscles is not permanently impaired by this section, which is best made with curved, dull-pointed scissors, and by cutting close to the bone all bleeding may be avoided. By retraction of the parts divided, a varying quantity of fat (the pre-vesical fat) is encountered lying on the anterior wall of the bladder and in contact above with the inferior fold of the peritoneum. With the finger nail (or, if necessary, the dull scissors) this fat is separated from the slight attachment to the inner surface of the ossa pubis, and also lifted upwards by the same means from the anterior bladder wall. In this manner the bladder is exposed for about two inches in its perpendicular axis, and the peritoneal fold is carried up with the fat, and is, as a rule, not seen. Only once or twice have I seen the peritoneum in my operations. The bladder is now in plain view, and the line of incision into the viscus is in sight. If any large veins are seen, and these are so located that their division is unavoidable, they should be tied with catgut passed beneath them, but not into the cavity of the bladder, by a small, curved Hagedorn needle. In order to keep control of and to support the bladder after its contents escape, and to serve as a guide to the introduction of the finger or any instruments, on either side of the proposed line of incision, a silk thread is inserted into the wall of the bladder by means of the Hagedorn needle. The thread being inserted, the needle is unthreaded, and the ends tied about one foot from the wound, leaving a movable loop. Everything is now ready for cutting into the bladder. A long, blunt retractor should be inserted on either side to hold the soft parts back, while a third shorter one draws the pre vesical fat apart, and with it the peritoneum. The silk loop being sufficiently tightened, a short knife is carried, the back downwards, in contact with the inner surface of the ossa pubis, until the point strikes the bladder about one-half inch below the level of the symphysis, when it is pushed through the anterior wall, which is rapidly incised in the median line upwards for one or two inches. As the injected solution escapes,

the finger is introduced and a thorough exploration effected. If for any reason the bladder is deeply sunk in the pelvis, the Barnes dilator may now be inserted per rectum, filled with 4-5 ounces of warm water, and by this means the floor of the bladder is lifted toward the wound. I have not had to resort to this expedient in more than three instances.

If a stone or foreign body is present, it may be removed with a light forceps or the finger. I find the index finger answers better than any instrument. When a tumor is present, it is easily recognized by the touch. The most satisfactory instrument for removing tumors of the bladder is a small fenestrated Spencer Wells ovarian sac clamp, the teeth of which have been filed off. With the finger tip resting on the tumor, the instrument is carried down with one jaw on either side of the finger until it slips from the finger tip on to the neoplasm. It is then pushed snugly on to the mass, the jaws closed, and the instrument twisted around and around until the tumor is twisted off. Any particles which may remain are in like manner removed. The retractors are now carried into the bladder, and thus stretching the wound wide open, will permit thorough sponging of the cavity and an ocular inspection of the walls. The Pacquelin cautery point may now be introduced, and the base of the neoplasm seared over. While this is not essential in ordinary prostatic hypertrophy of the middle or lateral lobes, it is imperative in malignant neoplasms and in papillomatous growths. If hæmorrhage is severe, it may be controlled by compression with warm sponges, or by water at 110-115° F. The after-treatment of the bladder will depend upon the condition of this organ. In all cases where cystitis exists from stone, foreign body, tumor or other cause, drainage is indicated, and, of course, where the urethra is impermeable or the bladder paralyzed, it is imperative. When no cystitis is present, it is advisable to close the wound in the bladder wall at once.

In only two of the twenty-three operations was an immediate suture undertaken, and in these cases the wound closed promptly without leakage. Both were in women.

A short, curved, small Hagedorn needle is armed with small, firm catgut (juniper oil gut is preferred). The edges of the incision in the wall of the bladder are brought up into the incision through the abdominal wall by traction on the silk thread already introduced, or by tenacula, and the sutures introduced in this manner. About $\frac{1}{8}$ of an inch from the edge of the incision the needle is carried into the wall of the bladder—not through it—and is made to emerge on the cut surface just where the mucous membrane rests on the muscular layer. It enters on the same level on the opposite side, and is carried out at the same distance from the edge of the

incision. The space between the sutures is from $\frac{1}{8}$ to $\frac{3}{8}$ of an inch. When all are inserted, they are tied and cut $\frac{1}{2}$ inch from the knot. The abdominal wound may now be stitched a short distance from its upper and lower angles, but as much as corresponds to the line of sutures in the bladder, is left open. A careful disinfection is now made, and the wound snugly packed with iodoformized gauze; bi chloride dressing over all. Should leakage occur, the open wound prevents all danger. A soft catheter should at once be inserted into the bladder by the urethra, and tied in. After three or four days, should irritation of the bladder or urethra supervene, it may be removed and reinserted at intervals to draw off the urine. In from seven to ten days the wound will be united sufficiently to permit the patient to empty the bladder at will. It is of great importance, however, that no urine should be allowed to accumulate within the first three or four days for fear of separating the edges of the wound.

In the majority of cases operated on, I have employed temporary drainage, and in two cases permanent supra-pubic drainage was established.

Temporary drainage is very satisfactorily secured by the Trendelenberg T tube, made of ordinary white rubber drainage tube, with a lumen of about $\frac{1}{4}$ of an inch. This tube is about ten inches long, one end being carried through a split in the center of a smaller piece of tubing about two inches in length, which is securely stitched to the larger piece. A single good-sized hole should be cut in the larger tube just at the level of the cross-piece. In inserting this tube, the cross-piece or top of the T should be folded back in the jaws of a pair of dressing forceps, and carried down to the bottom of the bladder, when, on loosening the forceps, the cross piece springs out and prevents the dislodgement of the tube. A final flushing of the bladder with boro-salicylic solution is now made, and the wound about the tube snugly packed with iodoform gauze. In doing this, while the tube should not be closed by pressure of the packing, it should be tight enough to keep air out of the bladder so the siphon-action of the tube may not be interrupted.

A smooth, well-adjusted piece of glass tubing about four inches long is now inserted into the rubber tube, and to this a long piece of rubber tubing is attached, the end of which leads into a vessel beneath the bed. To start the siphon-action the tube needs to be partially filled with water, after which the end is lowered, the water flows out, and the contents of the bladder follow. The outflow can be regulated by compression of the tube with a safety-pin, so that it falls into the vessel drop by drop just as fast as it is discharged into the bladder from the ureters. The patient for the first few days rests upon the back. The coil or loop of the drainage tube should be

secured to the dressing and the edge of the bed by safety-pins, so that it may not drag upon the wound. Should the tube become displaced, it may be reinserted, using the two silk loops left in the wall of the bladder on either side of the wound as guides.

Properly managed, the drainage by this method is perfectly satisfactory. I have had patients thus treated in whom the dressings did not get wet or have to be changed oftener than once in four or five days. There is no need, in my opinion, of an additional operation through the perineum to secure drainage by gravitation. At least, I have not felt the need for this method in any of my cases. The length of time the tube remains in the bladder will, as has been said, depend upon the condition of this organ. When the operation is done for removal of recent foreign body, or of a small tumor which has not caused cystitis and does not bleed much after removal, immediate suture of the bladder is indicated. When only moderate cystitis exists, should the urine clear off nicely in from three to seven days, the tube may be withdrawn. When this is done, a loose dressing of gauze and cotton is laid over the wound to absorb the urine which wells out. This will have to be changed at frequent intervals. In a few days the urine will partially flow out through the urethra, and by the end of from two to six weeks all will be discharged by the natural way.

Occasionally a small fistula may persist, which will require either to be packed with iodoformized gauze or scraped out with a Volkmann's spoon to insure its closure. In paralysis of the bladder, and in certain cases of obstruction either in the urethra or by hypertrophy of the prostate in which the bladder has lost so much of its tone that it can only empty a portion of its contents, leaving the remainder to press upon the rectum and to produce cystitis and discomfort, permanent supra-pubic drainage is indicated. This is best accomplished by a velvet rubber catheter arranged so that the eye-end, passed through the wound, rests easily upon the floor of the bladder. On the skin at the outer end of the fistula rests a shield of soft rubber, about $\frac{3}{8}$ of an inch in thickness and $1\frac{1}{2} \times 3$ inches surface measurement. It is held firmly in place by four pieces of tape attached to the four corners of the shield and tied two around the waist and two beneath the groins. The soft catheter is firmly moulded or soldered to the shield. In its outer end a small cork is inserted. As the urine collects sufficiently to demand evacuation, the bladder forces out a portion, and as soon as it ceases to exert power enough, the cork is removed from the catheter and the residue is then siphoned out. Patients wearing this tube enjoy great relief over their former condition, and can attend to work or social duties in comparative comfort.

In the present condition of my knowledge on this subject, I am deeply impressed with the safety and value of the *high operation*. For the thorough digital exploration of the bladder it is superior to *perineal cystotomy*.

The same is true beyond all question in the removal of tumors.

For drainage of the bladder, whether temporary or permanent, it answers every purpose.

For removal of stone or foreign body, to my mind it is so easy, safe and satisfactory that I prefer it to the low operation. In the light of my personal experience, I do not see why suprapubic cystotomy should not supersede all other methods of cutting into the bladder.

REPORT OF A CASE OF EXTRA-UTERINE PREGNANCY. RUPTURE INTO THE PERITONEAL CAVITY AT ABOUT THE FIFTH WEEK; OPERATION THREE WEEKS AFTERWARD. RECOVERY.

Read by Title in the Section of Obstetrics and Diseases of Women, at the Forty second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY RUFUS B. HALL, M.D.,

OF CINCINNATI, O.

SURGEON TO THE CINCINNATI FREE HOSPITAL FOR WOMEN. CLINICAL LECTURER ON GYNECOLOGY AT THE MIAMI MEDICAL COLLEGE ETC.

Mrs. M., aged 30, of Winton Place, married nine years, mother of three children, the youngest 5 years old. Three years ago had an abortion and some septic trouble following, since when she has had some pelvic trouble, and been under the care of several physicians. For the past year her health was somewhat improved, yet she was not well. December 29 the menstrual flow commenced, which was the twenty-eighth day. The flow stopped January 3, and was normal in every respect. February 1 she commenced to menstruate, and the flow continued seven days, but it was different from former periods, inasmuch as the flow continued an hour or two or half a day, and then stopped several hours, and during the whole period she suffered more pain than ever before during menstruation. From the 7th to the 12th she was quite free from pain, but on the 12th she had cramping pain in the lower part of the abdomen, coming on after a walk of some distance. This pain was quite severe, and grew gradually worse until the 15th, when the family physician, Dr. R. H. Whallon, was called on account of the pain in the abdomen, which was now very severe. The doctor visited her daily for four days, at which time she appeared to be convalescent, and said she was free from severe pain. She remained quite comfortable, requiring no medicine to relieve pain, and on the 22d she took a drive with some friends. On the 23d,

when in conversation with her mother, she suddenly grew very pale—this was so marked that it alarmed her friends, and they requested her to lie down. Although she had no severe pain at that time, yet the whole abdomen was sore and tender. The night of the 24th the patient got out of bed to use the commode, and fainted twice before her husband could get her on the bed again. She was never able to get up after that date until after the operation was made. After the 24th of February she had more or less pain all the time, with a sense of discomfort in the abdomen. March 1st to 7th she had a simulating menstruation discharge, and discharged shreds of decidua. March 8 there was first observed an enlargement in the left side of the abdomen, as large as the closed hand, which gradually increased in size. March 11 Dr. William H. Taylor was called in consultation, and diagnosed extra-uterine pregnancy, with rupture into the left broad ligament. On the 13th, Dr. E. W. Walker saw the case with Dr. Whallon, in Dr. Taylor's place, as the latter gentleman was unable to attend. On the 15th I saw the case with Drs. Whallon, Taylor and Walker. At that time there was an enlargement in the pelvis and left side of the abdomen as large as an adult head, which could be plainly outlined, extending diagonally across the abdomen from about two inches below border of the false ribs on left side, to midway between the anterior superior spine of the ilium and the pubic spine on the right. The uterus was in front of the mass, and pushed to the right side of the pelvis. The diagnosis of extra-uterine pregnancy with rupture into the folds of the broad ligament, which had been made four days previously, was believed by all present to be correct. But as the mass was increasing in size, and the patient losing strength, it was believed that an intra-peritoneal rupture would probably soon occur; therefore an immediate operation was advised. After a few hours to consider it, the family decided to have it made, and it was performed on the morning of the 16th. Present and assisting, Drs. Whallon, Taylor, Walker and Colter. When the cavity was opened, we came upon a mass in the abdomen which proved to be blood clot, as thick as jelly, and almost as black as tar. I felt first for the uterus, making certain that my hand went down upon the right side of that organ; by so doing I felt that I could better outline the parts, and as soon as the hand could be made to glide over the fundus I could at once grasp the tube near the uterus, on the side of rupture, and thus control hæmorrhage. By this method, I did not lose any time in definitely locating the parts. I first attempted to bring the tube into the incision, but the decidua became detached, and with some blood clot was removed. I at once secured the tube which formed the sac and tied it off. I now turned my attention to cleansing the abdominal cavity from blood clot, of which

there was an incredible amount, estimated to be about $4\frac{1}{2}$ pints. After thoroughly irrigating the cavity and placing a drainage-tube, the cavity was closed. The patient recovered without incident, and was able to sit up on the twentieth day after the operation. It is very difficult to say whether the rupture occurred on the 15th or the 24th of February, but it is a matter of scientific and practical interest to settle as near as possible; this, however, can only be approximate in this case. We are certain that it occurred as early as the 24th, if not on the 15th, and I am very strongly inclined to the opinion that it occurred at the time of her first severe pain, on the 15th.

It was probably the loss of blood that caused her to faint on the 24th. This belief is strengthened by the fact that on March 8 the abdominal enlargement was first observed, which would quite agree with the theory that the bleeding went slowly on during the interval, and the fluid portion being absorbed, leaving the blood clot, forming the enlargement. I recorded the case because these cases are always interesting, and to emphasize and illustrate a few facts in connection with this case which are of vast practical importance to the general practitioner and specialist alike. In this case there was not a single symptom or sign to lead one to believe that there was an intra-peritoneal rupture, yet the rupture was free under the peritoneal cavity, and not into the broad ligament, as we all believed before the operation. The pelvic floor was displaced downward, and the tumor was rounded and felt firm and fixed, as we would expect to find in a case of rupture into the broad ligament. This deceptive condition can now be explained in the following manner: The rupture occurred early at the end of the fourth or fifth week of gestation, near the middle of the tube, on its free border. This, at first, was probably quite small, and bled slowly, the more fluid portion of the blood being absorbed, leaving the blood clot, which the omentum and intestine became adherent to, closing off the greater portion of the abdominal cavity from contamination. As the bleeding continued, the intestine and omentum were crowded away from the left iliac fossa, but at the same time keeping the blood clot confined in that locality, thus making the apparent tumor. Adhesions of several weeks' duration were quite firm, and thus we can account for the depression of the pelvic floor simulating a rupture into the broad ligaments.

If we had waited for the absorption of that amount of blood clot, with the bleeding still going on, we would have lost our patient. The case demonstrates the difficulty attending a correct diagnosis as to intra- and extra-peritoneal rupture in extra-uterine pregnancy, as well as the danger of attempting the same—thus encouraging delay. We had in this case the very signs which are believed to be characteristic of rupture

into the folds of the broad ligament, when it was really a rupture free into the peritoneal cavity, as the specimens plainly show. With these facts before us, after we have made our diagnosis of extra-uterine pregnancy, are we to stand idly by and wait until we are certain the sac has ruptured into the peritoneal cavity, in any given case, before we recommend an operation? This is a very important question, and one that is by no means settled in the professional mind, but the careful study and report of these cases will soon settle this difficult problem. I now believe, if the case comes under observation before the fourth month, it is our duty to give the patient the best chance for her life; and that is an abdominal section, and that without delay. I here present the specimens in these three bottles. In the first one you will see the left tube, dilated into a sac the size of a small orange, with a rupture in the free border. In the second bottle you will find the decidua and blood clot. This clot, with the decidua and foetus, were in the tube at the time of the operation, and came away in my hand when I first attempted to bring the tube into the incision. The foetus, which is in the third bottle, was afterward found in the blood clot by Dr. Taylor, and as you see, is less than one inch in length.

RUPTURED UTERUS. OPERATION AND AMPUTATION OF A SECTION OF INTESTINE. A UNIQUE CASE.

BY H. WARDNER, M.D.,
OF CHICAGO, ILL.

Trusting the following report may be of interest, I send it to *THE JOURNAL*, in the hope that if there is a similar case on record, or having occurred in the practice of any physician, it may come to light. So far, I have not been able to find one in medical literature, or in the experience of physicians with whom I have conversed on the subject.

On Sunday, August 11, 1889, I was requested by my friend Dr. Dodds, of Anna, Ill., to visit with him a patient in a neighboring village, a young married woman, who seemed to be suffering from a delayed miscarriage, about which there was something unusual.

From the doctor, the patient and her husband, who was also a physician, I obtained in substance the following history of the case: On Wednesday evening, the 7th, she was at Anna, where, in running to catch the train just starting from the depot, she jumped and partly fell in getting aboard the car. She "felt something give away," and an uneasy feeling followed, coupled with more or less pain. After reaching her home, she spent the time up to nine o'clock playing croquet, although the bad feelings con-

tinued. At or a little after midnight she was taken with regular labor pains. She had all the symptoms of a miscarriage—the uterine contractions, the show of blood, and the presentation of a membranous sac at the mouth of the womb. (She had had a miscarriage some months previously at about the sixth month of gestation.)

The symptoms continued, with a great deal of suffering, until the Friday following, when Doctor Dodds was called to the case.

He found, on examination, a stringy substance resembling a cord, with membranes, and a tumor at the *os uteri* similar to that of a breech presentation or a *caput succedaneum*. He saw the case again on Saturday, the 10th, and finding her no better, but worse, and becoming exhausted, sought further advice.

I saw her, with Dr. D., Sunday afternoon. We found her lying upon her left side, limbs drawn up, face pinched and drawn in lines, indicating great internal suffering. She was pale and sallow; pulse 90, quick and thready. There was no swelling or enlargement of the abdomen, but the abdominal walls were rigid, as though the muscles were in a state of tonic contraction. She had been vomiting a greenish fluid for two or three days. The stomach was very irritable, retaining but little food or fluid of any kind.

A digital examination revealed a membranous, stringy mass, attached to a tumor lying partly within the uterus, with the larger part protruding into the vagina. The sensation communicated by the touch was similar to that of an encysted fetus of about two and a half months. She could not bear traction on this mass, saying "it hurt her stomach, and gave her severe pain in the head, which subsided as soon as traction ceased."

Upon examination with a speculum, and removal of the decomposing, bloody fluid present, that gave out a strong odor of the lying-in room, the stringy mass of tissue was seen to be in a sloughing condition, and very offensive. She was very sensitive to the manipulation. An anæsthetic was administered, when the mass was drawn down carefully and brought into view externally, when, to our great surprise, we discovered the form of small intestine. At this moment there was a discharge of a few drops of fecal matter. The opening into the gut was found in both upper and lower fragments, a strangulated loop having sloughed away. The stringy mass was mesenteric, and the tumor was the congested portion of the upper fragment of the intestine lying in the vagina between the *os uteri* and the slough. It was evident a loop of the small intestine had come down through the fundus of the uterus into its cavity, and that the organ had contracted, as in labor, to expel the intruding mass, producing strangulation and sloughing as a consequence.

The prognosis was unfavorable, and an early fatal result expected.

The dead parts of the gut were excised, and the patient put upon anodynes, and all the bland nourishment the stomach would bear.

After two or three days of depression, and more of the intestine having sloughed away, there was an effort of the system toward a rally of the vital forces. She had one passage from the rectum, clearing the lower fragment of the tube, and the feces from above passed per vaginam.

This condition gave rise to the faint hope that she might endure an operation for relief. Dr. John E. Owens, of Chicago, was called by telegraph, and came on the morning of the 20th. With him there were present at the consultation Drs. Ferrell, Vick, Dodds, Stocking, the husband of the patient and the writer.

The operation was decided upon, it being the only hope for relief, but with only a shadow of a chance for success.

The patient was placed on the table at 11:40 A.M., etherized, and Dr. Owen proceeded with the operation, assisted by the others present. The usual incision was made between the umbilicus and pubis. An abscess was found in the connective tissue between the bladder and the pubis. She had complained of vesical irritation and pain for three or four days. The ends of both fragments were found to be incarcerated in the uterus, and had become adherent to the walls of the opening through its fundus, so that it took considerable force to detach and remove them. On account of the doughy and lifeless condition, it was necessary to cut away three or four inches from each fragment. This involved, on the upper side, the removal of the ileo-cæcal valve and the lower end of the ascending colon. The ends were then stitched together by a combination of the Czerney and Lembert methods, the abdomen cleared and washed out with antiseptic solutions, and the wound closed; a drainage tube inserted through the uterus, and another left in the lower end of the abdominal wound.

The complications of the case made the operation necessarily tedious. About fifteen inches of intestine was lost by sloughing and excision.

The patient was placed in bed at 2:45 P.M., and died at 4 o'clock, one and a quarter hours later. There was no autopsy.

The severe pain in the head whenever traction was made on the protruding intestine is worthy of note as a means of diagnosis, should any one be so unfortunate as to meet with a similar case. All the other symptoms were those of a premature labor or a strangulated hernia.

What caused the opening through the uterine fundus? Possibly the wall was ruptured during the labor that occurred several months before. Possibly it was the result of an abscess. But I

have no satisfactory hypothesis to explain its existence.

If any physician knows of a case in medical literature or in practice similar to the above, he will confer a favor by informing me of it.

4106 Drexel Boulevard, Chicago, Ill.

TRANSLATION.

THE DIFFUSION OF THE POISON OF TETANUS IN THE ORGANISM.

At the meeting of the Société de Biologie of Paris, June 27, 1891, M. Camara Pestana presented the following note :

The symptomatology of tetanus is the consequence of the absorption of a toxine produced by the bacillus of Nicolaier, the latter remaining localized at the point of inoculation, as has been demonstrated by MM. Kitasato, D. Sanchez-Toledo, Veillon, and others. I have undertaken the study of the diffusion of the tetanic poison in the body, from the scientific standpoint, with the following results: The toxine which I employed was obtained from a pure culture of tetanus given me by M. Sanchez-Toledo, and which cultivated in bouillon, in the absence of air, was maintained at a temperature of 38° (100 4° F.) for nineteen days, and was then filtered through a porcelain filter. Control cultures made with the filtrate from the bouillon, and in gelatine, showed that the filter did not allow the passage of any bacilli; moreover, microscopic examination at the points where the injections of the filtered liquid were made, always showed the absence of the tetanus bacillus.

The experiments were made on guinea pigs and mice; the guinea pigs were used for the direct injection of the toxine obtained from the cultures; the mice were employed to determine the toxicity of the different organs of the guinea pigs injected with the toxine.

In the preliminary experiments I sought first to ascertain the effects of the liquid which I employed. One drop of toxine injected under the skin of the thigh of a guinea pig caused tetanus at the end of twelve hours, and death in twenty-four hours. One-twentieth of a drop produced in mice all the symptoms of the disease in eighteen hours, and death in thirty-eight hours.

The experiments were divided into these series, with the object of determining the toxicity of the different organs of the guinea pig :

1. At the moment of the appearance of the first symptoms of tetanus ;
2. After the generalization of these symptoms ;
3. After the death of the guinea pig.

In the first series of experiments I injected seven drops of toxine under the skin in the sacral region of the guinea pig. As soon as the first symptoms of tetanus were produced (contractions of the posterior members), I killed the animal by section of the carotid. The blood obtained was injected in different quantities under the skin of the mice. The following organs: kidneys,

liver, spleen, lungs, spinal cord, muscles of the region where the injection had been made, and muscles of the thigh, were removed with suitable precautions as to cleanliness, and in nearly equal weights. Each of these organs was finely triturated with a given quantity of physiological solution of sodium chloride. Then the effects of the emulsions of each of these organs on mice, were studied.

The symptoms of tetanus and death were produced uniformly in the mice who had received under the skin fifteen or more drops of blood, and also in those who had been inoculated with the emulsion of the muscles from the region of injection. The other mice presented no symptoms of tetanus.

In the second series, I killed the guinea pig after the development of all the symptoms of tetanus, that is to say at the time when the convulsions had become generalized. One cubic centimeter of blood, and one-half cubic centimeter of the emulsion of a small portion of the liver, produced tetanus, leading to the death of the mice at the end of 48 hours, with all the symptoms of the disease.

The emulsions prepared from the other organs and tissues produced no effect, except that from the muscles of the region injected, which always gave positive results.

Finally, in the third series of experiments, where I awaited the death of the guinea pigs before injecting the mice with emulsions of the organs, of the blood, and of clots found in the heart, I found that the liver only produced tetanus.

The phenomena are somewhat modified if the guinea pigs be injected with larger quantities of the filtrate from the cultures, 1.5 c.c. for example.

In the first series, the results were the same; but in the second and third series, tetanus was produced not only by the liver, and by the muscles of the injected part, but also by the spleen, the lung and the kidney. While the mice injected with the liver emulsion presented symptoms of tetanus in twenty four hours, and died at the end of thirty-six hours, those injected with other organs, presented the characteristic contractions only at the end of forty-eight hours.

Injections made with urine and the spinal cord, always gave negative results.

The following conclusions I believe to be justifiably drawn from the foregoing facts :

1. The absorption of the toxine of tetanus is made by the blood.
2. The lungs, spleen, kidney, but principally the liver, withdraw from the blood the poisonous principle, and retain it.
3. The toxine is not eliminated to any appreciable extent by the urine.
4. Notwithstanding the striking predominance of neuro-muscular phenomena in tetanus, the presence of the toxine in nervous and muscular tissue cannot be shown; all the experiments made with these tissues gave negative results.—*La Semaine Médicale*.

Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to
JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,

CHICAGO, ILLINOIS.
All members of the Association should send their Annual Dues
to the Treasurer, Richard J. Dunglison, M.D., Lock Box 1274, Phila-
delphia, Pa.

BY-LAW IV.—THE PUBLICATION OF PAPERS AND
REPORTS.

No report or other paper shall be entitled to publication in the
volume for the year in which it shall be presented to the Association,
unless it be placed in the hands of the Board of Trustees on or
before the first day of July. It must also be so prepared as to require
no material alteration or addition at the hands of its author.

Authors of papers are required to return their proofs within two
weeks after their reception; otherwise they will be passed over and
omitted from the volume.

Every paper received by this Association and ordered to be
published, and all plates or other means of illustration, shall be
considered the exclusive property of the Association, and shall be
published and sold for the exclusive benefit of the Association.

The Board of Trustees shall have full discretionary power to
omit from the published *Transactions*, in part or in whole, any paper
that may be referred to it by the Association, or either of the
Sections, unless specially instructed to the contrary by vote of the
Association.

SATURDAY, AUGUST 1, 1891.

THE SPECIFIC GRAVITY OF HUMAN BLOOD.

Since the discovery of the blood corpuscle and
the invention of the compound microscope, the
attention of hæmatologists has been almost
wholly directed to a study of the formed ele-
ments of the blood, while its general physical
properties and plastic elements have been largely
neglected. Especially has this been true of the
pathological relations of the blood; a brief
reference to our standard works on pathology
will show how infrequent are references to
changes in the physical properties of the blood,
and what is then said upon the subject is mostly
confined to the varying phenomena displayed by
coagulation. In part this defect has been due to
technical difficulties and to the small quantity of
blood available for clinical examination.

In 1884, ROY (*Journal of Physiology*) studied
the specific gravity of the blood after a method
devised by myself, and applicable to small quan-
tities of blood. The process was extremely
simple, consisting in the preparation of solutions
of a neutral salt of varying specific gravity. A
small mass of coagulated blood was then thrown
successively into each jar until a point was
reached when the blood would neither float nor

sink. It is apparent that this method was tire-
some and inaccurate, especially was the latter
true in cases where the normal coagulating
power of the blood was impaired.

SCHMALTZ (*Deutsches Archiv. für Klin. Med.*)
has described an instrument that is much more
convenient, and with which exact results are at-
tained with a small quantity of blood. It con-
sists essentially of a small glass tube 12 c.m.
long, ending in a capillary projection at both
ends. This is carefully weighed on a delicate
balance, it is then filled with distilled water and
weighed, and lastly with the blood to be exam-
ined. From the differences in these figures the
specific gravity may be readily calculated.

Recently DR. ERICH PEIPER (*Centralblatt für
Klin. Med.*, March, 1891), has contributed an
exceedingly interesting series of studies of the
specific gravity of blood, after the method of
SCHMALTZ. The blood of forty-nine healthy
persons was examined, of these twenty-five were
adult men, thirteen were adult women, eight
were boys and three girls. In adults the specific
gravity presented a range of from 1045 to 1066,
the average for men being 1055, and for women,
1053. The average for the children being 1052
and 1050 respectively.

The examination of the blood in 10 cases of
anæmia and chlorosis showed a distinct decrease
in the specific gravity, the variation being from
1030 to 1051, and the average 1042.

In most cases attended by asthenia and the de-
velopment of cachexia such as phthisis, carci-
noma, chronic gastritis and leukæmia, a marked
diminution in the specific gravity was found. In
six cases of advanced phthisis an average of 1042
was noted, while in five cases of beginning
phthisis, the figures were normal, 1055.

Of marked interest is the enormous lessening
of the specific gravity in cases of nephritis. A
boy ten years of age with parenchymatous ne-
phritis, showed only 1023, after four weeks and
marked improvement in the disease, the figures
rose to 1054. In two other cases of acute ne-
phritis, a specific gravity of 1030 and 1033 was
found. In cases of recent acute nephritis, the
figures were not materially lessened.

In cases of heart and lung troubles that were
accompanied by cyanosis, bronchitis, fatty heart,
emphysema and valvular lesions, a marked in-
crease in the specific gravity of the blood was

noted; the same was found to be true in febrile conditions, while in sub-acute and chronic rheumatism and diabetes but little change was observed.

We feel that the interest and importance of these observations merit special mention, and we hope that further studies will be made of this subject. It is perhaps too much to hope that these methods will be widely used in practice, as but very few physicians will have the time and patience to struggle with the technical difficulties; we can, however, look to our hospitals, with their well equipped laboratories, for a marked advance in our knowledge of the plastic elements of the blood, and a corresponding advance in our grasp of diseased processes.

MALPRACTICE.—DR. PARKER VINDICATED.

The Appellate Court of Illinois has just affirmed the decision of the Cook County Circuit Court in favor of the defendant in the case of *EDW. C. SIMS vs. ANDREW H. PARKER*. The plaintiff Sims, who is a mechanical engineer, doing heavy work, had been wearing, upon a physician's advice, a truss on the left side as a preventive for hernia. This was prescribed because of a pain which he felt in the left inguinal region in 1881. In March, 1888, he applied to DR. PARKER, who is a dealer in trusses, for relief from a similar pain on the right side. On examination DR. PARKER found an inguinal swelling which he pronounced a hernia, and fitted Sims with a double truss. From the beginning SIMS complained of the pain of the truss, but continued to wear it for about a month, when he became feverish and went to bed. He was confined to his bed about three weeks, at the end of which time the inguinal swelling had become as large as an egg, and in three weeks more had developed into an abscess seven inches long, the contents of which were evacuated by his attending physician, Dr. Snyder. Subsequently another abscess formed.

The contention of the plaintiff was that the truss had been improperly applied, and had produced the abscess. DR. SNYDER, who attended SIMS, testified that there was no pus, and no abscess prior to May 23, that is, two months after the truss was first applied. When pressed to give as his opinion that the truss had caused the abscess, he was of course unable to do so. DR.

HENRY HOOPER, who saw the patient in consultation with DR. SNYDER, May 23, testified that he found a large internal ring, but no hernia, and was unable to say whether a hernia had ever existed. In his defense DR. PARKER introduced many of the most prominent physicians and surgeons of Chicago, who testified to his great skill and ability as an adjuster of trusses, and to the impossibility of a truss producing an abscess. The gentlemen who testified in DR. PARKER'S behalf were DRS. A. J. BAXTER, MILTON JAY, RANSOM DEXTER, F. A. HUDSON, R. W. ISHAM, GEO. T. SPEARS, E. S. CROSS, N. S. DAVIS, J. R. MCCOLLOUGH, and ALLEN W. GRAY.

DR. PARKER testified that he had been engaged in the business of making, adjusting and selling trusses, since 1861.

The trial court took the case from the jury and decided in favor of the defendant on the ground that there had been no evidence introduced to show that the defendant was negligent or unskilful in his diagnosis or treatment. This action the Appellate Court approved.

The decision of the Appellate Court is of so much interest to the profession generally, that we publish it in full elsewhere in this issue of *THE JOURNAL*.

The decision indicates that a long established reputation, and the favorable consideration of the profession are not to be lightly overthrown.

The great importance of the decision to the profession we take it, is its emphasis of the doctrine that a mistake in diagnosis or an error in treatment is not sufficient to uphold a suit for malpractice. We are all human and must and do make mistakes in diagnosis, and in treatment. The complicated and incomplete data upon which physicians must base their judgments, make mistakes inevitable. No one but the charlatan is always right. But for negligence, and lack of average skill we may justly be held responsible, for these are errors which it is within the power of every qualified practitioner to avoid.

The profession, as well as DR. PARKER, is to be congratulated on the outcome of this case. But congratulations will not remunerate DR. PARKER for the unjust expenses to which he has been put, or for the worry and anxiety which he has had to undergo, nor for the actual although unjust, damage to his reputation, which every

professional man must suffer who is subjected to a malpractice suit. It is this last feature which makes it just to compel the plaintiff in a proposed malpractice suit, as is done in some States, to furnish bond to make good any damage which he may do the defendant in case his suit miscarries. In a case of real malpractice such provision would work no harm to the plaintiff, but it would prevent the filing of suits for blackmail or revenge, as is now so frequently done. It seems a little unjust to the medical mind that a physician must give bond before he attaches the property of a debtor, but that that debtor may turn around and attach the physician's reputation by a malpractice suit, in the most summary manner imaginable.

THE POISON OF TETANUS.

Last week we reviewed the etiology of tetanus, calling attention to the principal features of the bacteriology and chemistry of this disease, and particularly to the recent work which SANCHEZ-TOLEDO reported to the Société de Biologie. At the next meeting of this Society, June 27, 1891, CAMARA PESTANA reported the results of his very ingenious experiments relating to the chemistry of tetanus. A translation of his paper, as it appears in the report of the Society's proceedings in *La Semaine Médicale* of July 1, 1891, we present to our readers this week (see page 192), bringing the work on the etiology of tetanus up to date. Tetanus is particularly interesting, because the chain of events between the bacillus and the disease is here more fully revealed than in the case of any other disease. We do not mean to assert that the bacillus of NICOLAÏER has been shown to be the cause, and the only cause of tetanus, any more certainly than any other germ is shown to be the cause of a certain disease, for such is not the case. The right of KOCH's bacillus to the name bacillus tuberculosis, is established much more satisfactorily than the right of NICOLAÏER's bacillus to be called the tetanus bacillus. But the means by which the bacillus tuberculosis works is not known. Its chemistry yet remains to be revealed. Some of the chemical products of microorganisms which will produce diarrhoea, are known, but the bacteriology of the summer diarrhoeas of infancy, is still in a very tangled state. In the sense here indicated, it may be asserted that the scientific

completeness of the etiology of tetanus is exceptional.

PESTANA's paper, however, is of wider interest than the particular subject of which it treats. His experiments point out a convenient means of recognizing the distribution of the poison in a poisoned animal, when satisfactory chemical tests for the particular poison are unknown or not available. His experiments emphasize the importance of that function of the liver which consists in the withdrawal from the blood of poisons, and their destruction. His work also indicates that there is but little tendency on the part of the tetanic poison to escape by way of the kidneys. We hope that his work may be carried further to determine, if possible, the particular eliminative channel through which the tetanic poison most readily finds exit, or how its toxic effects are most certainly reduced within the body. We recently intimated in these pages that it would be of clinical importance to determine through what avenues given poisons might best be eliminated from the body. PESTANA's work gives a method by which such data may be experimentally determined.

PURE CULTURES.

By a pure culture is generally understood one which contains but one form of life, a single definite microorganism. This use of the term "pure culture" is justifiable so long as the use which is made of the culture is only morphological. Pure cultures of this type answer all requirements for the classification of microorganisms, for their morphological study. They might with propriety be termed "morphologically pure cultures." The absence of the limiting word, however, has lead to an improper idea of the purity of these cultures, and to a use of them for chemical purposes that is not strictly justifiable. Since the time when BRIEGER sewed such morphologically pure cultures in various media, and extracted therefrom the ptomaines formed, it has become customary to form similar cultures with pathogenic germs and to extract from them the poisons formed, so far, ptomaines or alkaloids, and toxalbumins, and to attribute the poisons so obtained to the biological activity of the germs. In the main, no doubt this conclusion is correct. But it is not necessarily correct.

The experiments of VAILLARD and VINCENT

with the tetanus bacillus referred to last week led them to believe that this bacillus formed an enzyme or unorganized ferment. Whether this be true or not, there can be but little doubt but that some microorganisms do produce such enzymes or soluble ferments. We do not wish to draw any hairsplitting distinctions between a germ and its enzyme, being willing to recognize that the chemical products of the enzyme are the chemical products of the biological activity of the germ. But herein lies the difficulty. The mechanical methods in vogue of separating germs from each other, and securing morphologically pure cultures of individual microorganisms, afford no guarantee that there has not been carried along with one germ, some of the enzyme of another to contaminate the resulting culture. A culture then may be pure, morphologically, but at the same time be contaminated with the enzyme of another germ. It is not a chemically pure culture.

It is true that an enzyme can not multiply while the organized ferment, the germ, can, so that in succeeding cultures, absolute purity may be obtained. But the infinitesimal amount of an enzyme which is necessary to produce a fermentation, and the uncertainty which attends the determination of its presence or absence in cultures prepared in the ordinary way, must necessarily throw a cloud over chemical deductions made from such cultures.

At least two ways are open to prepare cultures free from the enzymes of other germs.

If a culture be placed in a porcelain filter it may be washed with as much water under pressure as may be necessary to thoroughly cleanse it. The water will dissolve all enzymes and carry them through the filter, while the bacilli themselves remain.

So far as known all enzymes are chemically related to the proteids, at least they are rendered inert by a temperature a little short of the boiling point of water. Adult bacilli are likewise destroyed by a like temperature, but spores are not. So that with all sporulating microorganisms, heat could be used to destroy the enzymes and adult bacilli, and leave the spores to develop into cultures which would be pure in reality.

It is therefore urged that all cultures whose chemical products are to be investigated, should first be rendered pure, chemically as well as morphologically.

THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

In no other direction is the activity of thought and observation among medical men so perceptible as in the growth of interest in their societies. Last week it was our sincere pleasure to direct attention to the meeting next month in Washington of the Congress of American Physicians and Surgeons. Only a month later, in October, will be convened in St. Louis the Mississippi Valley Medical Association. The former is a gathering of specialists, the latter is distinctively a society of general practitioners.

Politicians and political economists often refer to our agricultural brethren as constituting the bone and sinew of our country, so we may without offense speak of the general practitioners of medicine as constituting the backbone, ribs and bosom of our art. They are the all-round men, who are called upon at all hours and seasons, to skilfully treat an inflamed corn, a flooding uterus, a fractured skull, or any of the other ills that afflict humanity—and rarely indeed is the record made, that they were not equal to the occasion.

These are the men who will gather at the Pickwick Theatre in St. Louis, on the morning of October 14, and continue in session until the close of the afternoon of the 16th. Nor will the general practitioners be allowed to become lonesome or to absorb all the good things of the occasion, for there is not a specialist within a thousand miles of St. Louis who is not perfectly familiar with the multitudinous advantages that just roll in upon him, through an attendance at the annual meetings of the Mississippi Valley Medical Association, and—he'll be there.

This year the President of the Mississippi Valley Medical Association is Dr. C. H. Hughes. The hundreds of physicians in the Valley who know Dr. Hughes will every one of them go to this meeting, that is a foregone conclusion, and the other hundreds who don't know him should be advised, and advised strongly, to go and make his acquaintance. Dr. I. N. Love is chairman of the Committee of Arrangements. This announcement means that every detail for the accommodation and entertainment of the members will be amply—fully provided for. There will be no slips or unforeseen contingencies. While the entire profession of St. Louis regard the Mis-

Mississippi Valley Medical Association as very much their own organization.

The working methods of the Mississippi Valley Medical Association are of such a character as to commend it to every man who practices the healing art; and every physician who practices rational medicine and is in good standing with his professional neighbors, is eligible and welcome to its membership. The only fees are one dollar per year. The man who goes once, is forever after a confirmed *habitué*, besides that, he becomes a regular missionary in his zeal in endeavoring to get others to go to the next meeting.

Furthermore, an attendance on a meeting of the Mississippi Valley Medical Association is just about as good an outing as a practitioner of medicine can take at that particular time of the year.

Decision of the Appellate Court in the Case of Edward C. Sims vs. Andrew H. Parker, M.D.

Edward C. Sims, Appellant, vs. Andrew H. Parker, Appellee. Appeal from the Circuit Court of Cook County. Moran, P. J.

This action was brought to recover damages for an injury alleged by appellant to have been caused to him by a truss improperly applied and adjusted to him by appellee for the cure of hernia, when in fact, he had no hernia.

At the close of the evidence at the trial, the Court directed the jury to find a verdict for the defendant.

Plaintiff had for some years worn a truss on one side, and in March, 1888, feeling certain pains, he went to defendant's place of business, and told his symptoms, and afterwards was examined by defendant, who told him that he was ruptured. Thereupon plaintiff purchased a truss from defendant, and had him adjust it to his person.

After the truss was put on plaintiff suffered great pain, and went back to defendant several times, complaining of the pressure of the truss, and plaintiff readjusted the truss and told him it was necessary to have pressure in order to effect a cure of the alleged hernia. After wearing the truss about two weeks, plaintiff became sick, and an abscess appeared at the point where the bulb of the truss had pressed.

The evidence shows that the plaintiff suffered great pain from the abscess, and was sick for a long time, and his contention is, that the abscess was the result of the too great pressure of the truss produced by the improper adjustment thereof to his body. It is shown that plaintiff was very fleshy; that at the point where he located the pain which he complained of, when he first went to defendant, there was a slight swelling or protuberance, and that over this defendant adjusted the bulb of the truss. When the truss was taken off at the end of two weeks this swelling had increased, and as before said,

developed into an abscess. The physician who attended plaintiff and who was a witness on trial, was unable to say whether there was an incipient abscess at the time the truss was first adjusted, or whether the abscess was produced by the pressure of the truss.

The fair result of the evidence of the experts sworn is, that there was in fact no rupture on the person of plaintiff, but it is also proven that it is very difficult to tell, with certainty, in many instances, whether in fact there is hernia or not, particularly in the case of fleshy persons.

Defendant introduced a number of leading surgeons and physicians of the city, who testified to the reputation and skill of defendant in treating hernia, and in fitting and adjusting trusses.

While there is evidence tending slightly to support the contention that the abscess may have been produced by the pressure of the truss, there is absolutely no evidence that defendant was negligent or unskilful in his diagnosis or in fitting the truss.

Proof that he was mistaken as to the existence of a rupture, or that the abscess was caused by the pressure of the truss, was not enough to entitle plaintiff to a verdict.

Proof of a bad result or of a mishap is of itself no evidence of negligence or lack of skill. The defendant is qualified to practice medicine and surgery, and the evidence of the experts in his profession shows him competent and skilful. Before a recovery could be had against him, it must be shown that his treatment was improper or negligent, not merely that he was mistaken, or that his treatment resulted injuriously to plaintiff. A physician or surgeon, or one who holds himself out as such, is only bound to exercise ordinary skill and care in the treatment of a given case, and in order to hold him liable, it must be shown that he failed to exercise such skill or care.

McNevin vs. Lowe, 40 Ill., 209.

The jury cannot draw the conclusion of unskilfulness from proof of what the result of the treatment was, but that the treatment was improper must be shown by evidence.

"No presumption of the absence of proper skill and attention arises from the mere fact that the patient does not recover, or that a cure was not effected."

Haire vs. Reese, 7 Philadelphia: R., 138.

No man, skilled or unskilled, undertakes that he shall be successful; "he undertakes for good faith and integrity, but not for infallibility, and he is liable to his employer for negligence, bad faith or dishonesty, but not for lapses consequent upon mere errors of judgment."

Cooley on Torts, 777.

Holtzman vs. Hoy, 118 Ill., 534.

Proof of the lack of skill or negligence on the defendant's part—a necessary element in plaintiff's case—being entirely lacking, the Court properly instructed the jury to find for the defendant.

The judgment must be affirmed.—*Affirmed.*

In Testimony Whereof, I have set my hand and affixed the seal of the said Appellate Court, at Chicago, this twenty fifth day of July, in the year of our Lord one thousand eight hundred and ninety-one.

THOMAS G. McELLOGOTT,
Clerk of the Appellate Court of the First District.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

A Chinaman, named Hop Sing, presenting a well marked case of leprosy of the tubercular variety, who has for some time past been running a laundry on the east side of the city, was recently discovered by the Board of Health, and when the announcement was made of the nature of his disease there was considerable consternation in the neighborhood. It seems that the man came to New York about a year and a half ago, and it is probable that he was then already affected. When his fellow countrymen living in the Chinese colony in Mott street, found that he was suffering from leprosy, they raised \$200 to send him back to China, but he simply removed to Newark, New Jersey, and with the money opened a laundry there in connection with another leprosy Chinaman. Eight months ago, however, he returned to New York and established himself in the location mentioned.

As soon as the existence of the case became known the Health Department made an investigation, and Dr. Dillingham, of the Bureau of Contagious Diseases, pronounced it one of undoubted leprosy. For a few days, however, nothing was done in regard to it, as the danger of infection was not regarded as urgent. On the return of Dr. Cyrus Edson, Chief of the Bureau, who had been absent from the city, the patient was removed to Charity Hospital on Blackwell's Island. In regard to leprosy in this city Dr. Henry G. Piffard, the well-known dermatologist, some time ago made an interesting report from which the following is an extract:

"During the past twenty-five years there have been probably fifty or sixty cases in the city of New York. Of these cases I have personally examined probably twenty five or thirty. With but one exception these cases came from abroad, that is from countries where leprosy is endemic and prevalent. There is at the present time, I believe, a case in the Charity Hospital which has been there for years, but no cases have arisen in this city by contact with any of the afflicted, as far as known to me. In view of the fact that there are rarely more than two or three cases of leprosy in the city at the same time, and the fact that the liability to infection is so slight, it seems to me that it would be hardly worth while for the Health Department at the present time to exercise any supervision over lepers other than to keep a record of their location and surroundings as carefully as possible."

Since 1866, five deaths from leprosy have been reported in New York: one in 1873, one in 1875, one in 1879, one in 1881, and one in 1884.

The fact of Hop Sing's case having been made public naturally directed attention to that of his fellow countryman in New Jersey, with whom he became temporarily associated when he left this city. Dr. Saltanstill, Inspector of the Hudson County Board of Health, after carefully examining the man has pronounced his disease leprosy, and has so reported to the Board.

At the Maternity Hospital on Blackwell's Island, an "incubation" for the preservation of premature and other

infants of low vitality was lately received from Paris, and the first case, a premature child weighing only four and a half pounds, has been very successfully "hatched out" in it. It is announced, however, that at the Woman's Hospital in Philadelphia, two of these incubators have been in use for the last three years, and that during the past year they have been employed in no less than fifty cases, all of which are now living. One of these is said to be quite remarkable, it being that of a six months child. The apparatus, which may not be familiar to all the readers of THE JOURNAL, consists of a ventilated wooden box, containing a perforated mattress, supported by iron rods, on which the infant, wrapped in cotton, is laid, the required heat being furnished by means of hot water bottles placed under the mattress. Daily inunctions with codliver oil are usually employed instead of bathing with water.

By the will of the late Hector C. Havemeyer, who died in 1880, \$200,000 was bequeathed to various charitable institutions in this city; the selection of these being left to his mother. She has now announced those which she has chosen, and among them are the Manhattan Eye and Ear Hospital, which is to receive \$35,000; the New York Eye and Ear Infirmary, which gets \$10,000, the Presbyterian Hospital, \$5,000, and the New York Post-Graduate Medical School and Hospital, which also gets \$5,000.

New York has just lost two of her most venerable and highly respected physicians. One of them, Dr. John Ledyard Vaudervort, who for more than fifty years was the librarian of the famous medical library of the New York Hospital, having been appointed to the position in 1837. At the time of his death, he was in the 83d year of his age, but for about twelve years he had not been in active practice. He was an old time New Yorker, having been born and spent all his life in this city. He was a graduate of Columbia College, and of the College of Physicians and Surgeons.

The other was Dr. Orid P. Wells, who died at the ripe age of 86. He was born in Berkshire County, Massachusetts, but came to New York when quite a young man to practice. In the cholera epidemic of 1832, he did such good work that when the epidemic of 1849 occurred, he was placed in charge of the cholera hospital. Prior to the establishment of the Board of Health he was also City Physician for a time. During almost his entire residence in this city, his home was on West 20th street, and it is said that when he first occupied it there was no brick house except his own north of Washington Square. His funeral services were held at the neighboring church of St. Peter's, where for many years he was a devout worshiper. Dr. Wells was one of the founders of the New York Academy of Medicine, and of late years had been an honored member of the County Association. P. B. P.

Dear Sir:—At bottom of page 21, of THE JOURNAL of July 4, is an item headed "The oldest and largest Medical Society in the United States." The Massachusetts Medical Society, founded in 1781, and now having about 1800 members, might perhaps come nearer to that mark than the Society named in the item.

Respectfully, J. L. WILLIAMS.
Boston, July 7, 1891.

BOOK REVIEWS.

THE FIRE PROTECTION OF HOSPITALS FOR THE INSANE. By L. H. PRINCE, M.D. Chicago: C. H. BLAKELY & Co.

Nothing can be more appalling than a fire in a crowded hospital, filled with the sick or insane. Abundant experience in the past has shown the frequency of these accidents and the inadequate means at hand for dealing with them. We feel sure that the day is not distant when the herding of large numbers of sick and helpless people, in non-fire-proof structures will be considered little less than criminal. Until that time comes every possible precaution should be taken by the organization of a special fire brigade in every institution for the sick and defective classes. This brigade should not only be thoroughly drilled in the most approved methods of fighting fires, but a life saving corps should form part of such fire service.

It is to the solution of this problem that this small work is addressed. A summary of the chapter headings will give an idea of its scope; the prevention of fire, fire extinguishing apparatus, the fire alarm, the fire brigade, drilling of the brigade, the fighting of fire.

While, as the author says, much more is to be learned in such matters from experience and practice than by the mere reading of books, yet the work contains much that will be invaluable in organizing the fire service of any public institution. The writer has developed his ideas by practical experience, having organized the fire service at the Illinois Eastern Hospital for the Insane, one of the best, if not the best in this country. A copy of this work should be in every public institution for the defective classes.

MISCELLANY.

DR. J. P. CROZER GRIFFITH, Professor of Clinical Medicine in the Philadelphia Polyclinic, has also been elected Clinical Professor of the Diseases of Children in the University of Pennsylvania.

HARVARD MEDICAL SCHOOL FELLOWSHIPS.—Three scholarships of \$5,000 each have been established through the gift of William S. Bullard.

DR. NATHAN BOZEMAN—The University of Alabama, at its recent commencement occasion, conferred the degree of LL.D. on this well-known surgeon.

THE UNIVERSITY OF VERMONT.—Dr. Condict W. Cutler, of New York, has been appointed professor of skin and venereal diseases, to succeed Dr. R. W. Taylor, who has resigned.

DR. W. W. KEEN, of Jefferson Medical College, recently received the honorary degree of LL.D. from Brown University.

AMERICAN DERMATOLOGICAL ASSOCIATION.—The following additional papers will be read at the next annual meeting of this Association, to be held in Washington, commencing September 22:

"The Hypodermic Use of Hydrargyrum Formamidatum in Syphilis," by Dr. R. B. Morison.

"Retarded Hereditary Syphilis," by Dr. R. B. Morison.

"Epilation; its Range of Usefulness as a Dermatotherapeutic Measure," by Dr. J. Zeisler.

ILLINOIS STATE DENTAL SOCIETY.—At the twenty-seventh annual meeting of the Illinois State Dental Society, held at Bloomington, May 12 to 15, 1891, the following officers were elected for the ensuing year: W. H. Taggart, Freeport, President; Garrett Newkirk, Chicago, Vice-President; Louis Ottofy, Chicago, Secretary; W. A. Stevens, Chicago, Treasurer; F. H. McIntosh, Bloomington, Librarian.

The next meeting will be held in Springfield, beginning on the second Tuesday in May, 1892.

LOUIS OTTOFY, Secretary,
70 Dearborn St., Chicago, Ill.

DR. DANIEL G. BRINTON.—Dr. Brinton, so long known for his surgical work, and his former connection with the *Philadelphia Medical and Surgical Reporter*, has received the degree of LL.D from the Jefferson Medical College, in recognition of his researches in anthropology and ethnology.

ST. LOUIS MEDICAL COLLEGE has been made the Medical Department of Washington University.

PHILADELPHIA'S POLYCLINIC.—The Board of Trustees of the Philadelphia Polyclinic and College for Graduates in Medicine have created a third Chair of Diseases of the Eye, and, upon the unanimous nomination of the Faculty, have elected Prof. George de Schweinitz, M.D., to fill the position.

UNIVERSITY OF MICHIGAN.—Dr. Victor C. Vaughan is made Dean of the Faculty of Medicine in succession to Dr. Ford who has resigned.

MILITARY ORDER OF SURGEONS OF NEW JERSEY.—At the regular meeting of the Military Order of Surgeons of New Jersey, held at Sea Girt, N. J., June 15, the following officers were elected: President—Lieut.-Col. A. K. Baldwin, Surgeon, First Brigade. First Vice President—Lieut.-Col. Franklin Gauntt, Surgeon, Second Brigade. Second Vice-President—Col. George W. Terriberry, Division Surgeon. Secretary—Major E. L. B. Godfrey, Sixth Regiment. Treasurer—Major H. C. H. Herold, Fifth Regiment. The following were elected honorary members of the Order: Surgeon-General Jos. D. Bryau, New York; Surgeon-General Nicholas Senn, Illinois; Major Alfred A. Woodhull, Surgeon U. S. A.; Major John H. Janeway, Surgeon U. S. A.

THE STANDARD DICTIONARY.—From an inspection of advanced sheets, we are led to believe this will be one of the most valuable works ever offered to English speaking people. It is worthy of the highest commendation.

ASSOCIATION OF AMERICAN PHYSICIANS.—The sixth annual meeting of this Association will be held in connection with the second Congress of American Physicians and Surgeons, at Washington, D. C., September 22, 23, 24 and 25, 1891.

Tuesday, September 22. Session of the Association, 10 A.M.

1. President's Address, William Pepper, of Philadelphia.

2. General Business, Reports, etc.

3. Discussion on the Treatment of Visceral Tuberculosis by Koch's Method. Reports by F. P. Kinnicutt, of New York; Harold C. Ernst, of Boston; William Osler, of Baltimore; Drs. Musser and Griffith, of Philadelphia.

4. The Climate of Southern California for Respiratory Diseases. A Preliminary Paper, Norman Bridge, of Los Angeles.

5. Experimental Studies on the Causes of the Localization of Pulmonary Phthisis and certain other Infectious Diseases in the Lungs, J. W. Roosevelt, of New York.

Session of the Congress, 3 P.M. Conditions Underlying the Infection of Wounds, including a Discussion of Disinfection with reference to the Treatment of Wounds, of the Relation of Bacteria to Suppuration, of the Resistance of Tissues to the Multiplication of Bacteria, and of the Effects of Antiseptic Agents on Wounds.

Referee—Dr. William H. Welch, of Baltimore, Professor of Pathology, in Johns Hopkins University.

Co-Referee—Dr. Roswell Park, of Buffalo, Professor of Surgery in the Buffalo Medical College.

The discussion will be adjourned, if necessary, until Friday afternoon.

Wednesday, September 23. Session of the Association 10 A.M.

6. Discussion on the Remote Results of the Removal of the Ovaries and Tubes.

Referee—William T. Lusk, New York.

Co-Referee—Wharton Sinkler, of Philadelphia.

7. Nerve Stretching in Invertebrate Cases of Trigeminal Neuralgia, James Stewart, of Montreal.

8. On the Diseases of the Kidney, popularly called "Bright's Disease," Francis Delafield, of New York.

9. Note on the Recognition of Certain Cases of Epilepsy, accompanied by Albuminuria, which might be mistaken for Cases of Uræmic Convulsions, James Tyson, of Philadelphia.

10. Bradycardia in Acute Articular Rheumatism, I. E. Atkinson, of Baltimore.

Session of the Congress, 3 P.M. The Late Manifestations of Syphilis.

Referee—Dr. Phineas S. Conner, of Cincinnati, Professor of Surgery in the Medical College of Ohio.

Co-Referee—Dr. Abner Post, of Boston, Clinical Instructor in Syphilis in Harvard University.

The President's Address will be delivered in the Lecture Hall of the National Museum at 8 P.M., and will be followed by the Reception of the President from 9:30 to 12 P.M.

Thursday, September 24. Session of the Association, 10 A.M.

11. Discussion on the Relations between Arterial Disease and Visceral Changes.

Referee—George L. Peabody, of New York.

Co-Referee—W. T. Councilman, of Baltimore.

12. Intestinal Perforation in Typhoid Fever, R. H. Fitz, of Boston.

13. The Relation of Drinking-Water to Disease, Henry P. Walcott, of Cambridge.

14. A Contribution to the Pathology of Pernicious Anæmia, J. P. Crozer Griffith and Charles W. Burr, of Philadelphia.

15. On Changes in the Red Blood Corpuscles in the Pernicious Anæmia of Texas Cattle Fever (by invitation), Theobald Smith, of Washington.

Session of the Congress, 3 P.M.

Fibroid Processes (Chronic Interstitial Inflammation Scleroses); their Pathology and Etiology, with Special Reference to the Influence of Diathesis and Heredity.

Referee—Dr. A. L. Loomis, of New York City, Professor of Pathology and the Practice of Medicine in the University of the City of New York.

Co-Referee—Dr. William Osler, of Baltimore, Professor of Medicine in Johns Hopkins University.

Dinner, conjointly with the American Surgical Association, in honor of our Foreign Guests, at the Arlington Hotel, at 8 P.M.

Friday, September 25. Session of the Association, 10 A.M.

16. The Condition and Prospects of the Library of the

Surgeon-General's Office, and its Index Catalogue, John S. Billings, of Washington.

17. Sequel to a Case of Slow Pulse (Purdy), D. W. Prentiss, of Washington.

Report of Autopsy, Robert T. Edes, of Washington.

18. Grave Forms of Purpura Hæmorrhagica, J. H. Musser, of Philadelphia.

19. Pathological Histology of Acute and Chronic Appendicitis, William F. Whitney, of Boston.

20. The Treatment of Typhoid Fever by Systematic Cold Bathing, James C. Wilson, of Philadelphia.

21. Concluding Business.

Session of the Congress, 3 P.M. If necessary, the discussion on the "Conditions Underlying the Infection of Wounds," etc., will be resumed.

General Information.—Drs. James G. Glover and William M. Ord, of London; Drs. McCall Anderson and W. T. Gairdner, of Glasgow; Dr. J. Batley Tuke, of Edinburgh; Professor Curschmann, of Leipzig; Professor Kühne, of Heidelberg; and Dr. Löwenberg, of Paris, have already accepted the invitation of the Association to attend the Congress, and will be the guests of the Association, and will participate in the discussions of the papers read before it.

The Association will hold its meeting in Hall No. 1 of the Grand Army Building, 1412 and 1414 Pennsylvania Avenue; and in the Main Hall of the same building the meetings of the Congress will be held.

Members of this Association are *ipso facto* members of the Congress, and as such are expected to register. Parlors 1 and 2 in the Arlington Hotel will be provided for that purpose, from which the mail of the members and guests will be distributed, and at which the city residence of each member or guest can be ascertained. The registration fee is five dollars.

A copy of the transactions of the Congress will be sent to each person who may register; and only those who may register, invited guests, and ladies accompanying them, will be admitted to the Reception of the President.

Dr. Samuel C. Busey is the representative of this Association on the Committee of Arrangements, of which he is Chairman.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from July 18, 1891, to July 24, 1891.

Capt. Reuben L. Robertson, Asst. Surgeon U. S. A., ordered for duty to Ft. Niagara, N. Y., on the abandonment of Ft. Abraham Lincoln, N. Dak.

Asst. Surgeon William L. Kneudler, U. S. A., granted leave of absence for one month.

Surgeon Henry R. Tilton, U. S. A., granted leave of absence for two months on surgeon's certificate of disability.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending July 25, 1891.

Asst. Surgeon James G. Field, ordered to special duty in the Bureau of Medicine and Surgery.

Asst. Surgeon James S. Hope, ordered to the receiving ship "Franklin."

Asst. Surgeon Lewis Morris, ordered to the "Ajax" and other monitors, Richmond, Va.

Asst. Surgeon James F. Keeney, promoted to P. A. Surgeon.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Three Weeks Ending July 18, 1891.

Surgeon R. D. Murray, to proceed to Gulf Quarantine for temporary duty. July 1, 1891.

Surgeon H. W. Sawtelle, relieved from duty at Portland, Me., ordered to Boston, Mass. July 11, 1891.

Surgeon Fairfax Irwin, when relieved at Boston, Mass., to proceed to Buffalo, N. Y., for temporary duty. July 11, 1891.

P. A. Surgeon H. R. Carter, ordered to Washington, D. C., for temporary duty. July 2, 1891.

P. A. Surgeon C. T. Peckham, granted leave of absence for seven days. June 30, 1891.

P. A. Surgeon S. C. Devan, when relieved at Buffalo, N. Y., to proceed to Portland, Me., for duty. July 11, 1891.

P. A. Surgeon S. D. Brooks, granted leave of absence for thirty days. July 13, 1891.

P. A. Surgeon J. J. Kinyonn, granted leave of absence for thirty days. July 14, 1891.

Asst. Surgeon E. A. Houghton, to proceed to Cleveland, O., for temporary duty. July 8, 1891.

ORIGINAL ARTICLES.

PLATINUM NEEDLES FOR ELECTROLYSIS.

Read before the Section of Surgery and Anatomy, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY ROBERT NEWMAN, M.D.,

OF NEW YORK.

CONSULTING SURGEON TO HACKENSACK AND BAYONNE HOSPITALS, ETC.

It is at present difficult to procure a small sized platinum needle, which is in every respect satisfactory to the operator.

The needles on the market are deficient: for instance, the insulation is rough, uneven, and not smooth on an equal plane from the non-insulated point, to and over the beginning of the insulation, the point is too dull, and will not readily pass through cuticle and fascia; the non-insulated part is weak, and breaks off easily; the shaft, or the whole needle is not stiff enough to be easily pushed into the tissues, and on any attempt at use will bend. The shape of the point is also objectionable, and makes a hole at the point of entrance, instead of cutting evenly and pushing through the tissues more by dilatation, than in such a manner, so that on withdrawal of the needle the point of entrance contracts again, without leaving a bleeding surface.

USE OF NEEDLES.—With the progress and better understanding of electricity in Surgery the use of needles in electrolysis will increase. So far they have been used in the following diseases: Aneurism, varicocele, hydrocele, nævi, portwine marks, angioma, erectile tumors, epilation, xanthoma, ranula, hernia, bronchocele, different tumors, carcinoma, diseases of the prostate, ovarian tumors, fibroids, peri-uterine hæmatocele, salpingitis, hydrosalpinx, and others.

The enumeration of these diseases, in which electrolysis with needles has been used, is made here only as statistical facts, with no intention to elicit a discussion as to whether or not in special cases electrolysis is the best means of treatment. It is a fact, that electrolysis with needles has been used often in a variety of diseases. The probability is, that in the near future, this procedure will be practiced oftener; and therefore

the point at issue is, that it is important to procure good needles, if an operation by electrolysis is intended.

The action of electrolysis is principally a chemical decomposition. If, for instance, chloride of ammonium be decomposed by electrolysis, the chlorine liberated at the positive pole will react upon some of the remaining salt, giving free nitrogen and chloride of nitrogen. If iodide of potassium in solution be subjected to electrolysis, one equivalent of iodine liberated at the positive pole will also have one equivalent of hydrate of potassium liberated at the negative pole, showing that the potassium liberated from combination with the iodide has combined with some of the surrounding water. Potassium and sodium are liberated in a nascent state, combining with the oxygen, thus forming compounds, as caustic soda and potash.

If needles are used for electrolysis this chemical action takes place in the tissues, as well as in the needles; the needles themselves will suffer this chemical decomposition in such degrees as the metal used has the capacity of an electrolyte. If, for instance, zinc needles are used, chloride of zinc will form and remain in the tissues and act as a caustic. All metal needles will oxidize at the positive pole. The knowledge of the decomposition of metals by electrolysis has been used practically by trades and arts and in electro-metallurgy. The electrolytic action is mostly polar, that is the elements liberated will collect at their respective pole, and may extend within a certain radius around the pole. It seems, there is no inter-polar electrolysis; that means while the molecular action travels between the poles, no alteration of tissues or cells has been found in the intervals between the poles, and the changes were confined to the poles and their surroundings. In experiments made I found the action of electrolysis extended to $1\frac{1}{2}$ inches around the poles.

These brief remarks of the electrolytic action on needles will suffice to show how important is the selection of the metal for needles. In some operations the negative needle may be of steel, for others the operator may prefer any other metal to carry out his particular intentions. There are many cases, in which it is essential to use a needle of metal, which neither oxydizes or decomposes

by the electrolytic action. There is only one metal which has all the qualities necessary in such cases, that is platinum. It is not in the scope of this paper to discuss what kinds of metal should be used in the different operations; the only object is to show how platinum needles should be made, in order to answer their purpose.

Platinum is a metal of the color of silver, but less bright. Its specific gravity is 20. It is harder than iron, undergoes no alteration in air, resists the action of acids, and can be rolled into thin plates and wire. It is also ductile, which is the only drawback to its use under consideration. The needles are very flexible and bend easily; for the same reason it is difficult to make a sharp point which will readily penetrate the tissues. If needles of a large size can be used, we have no difficulty, and platinum answers well, but the trouble begins when a needle of a small size is required to be introduced into small nodules, through tough tissues.

Here are some samples of the deficiencies. The needle is often too flexible, and the point dull and fragile, so that on an attempt to penetrate the tissues it either bends or breaks, or the insulation is insufficient and rough. Instrument makers make either or all these errors.

A perfect insulation is made in New York at one place only, viz.: that of Geo. Tiemann & Co., but their beautiful insulation as a rule weakens the needle, though lately that error has been to a considerable degree corrected.

A good needle for our purpose must possess the following qualities:

1. It must be of a small size, in order to enter dangerous anatomical places, without injuring vessels, etc.
2. There must be stiffness, which enables the operator to push through cuticle and fascia into tumors without bending.
3. The point must be sharp, entering the tissues without causing hæmorrhage, a wound or slough.
4. The whole needle with a perfect insulation must be even and smooth.

It will be perceived that the construction of the ideal platinum needle of small size offers many difficulties, which are not easily overcome. Only those who have experienced failures, understand what resistance the tissues offer to the entrance of the needle, and what force is needed to push the needle to the desired position. First are the cutaneous surfaces, which offer resistance and often the point breaks, the shaft bends and the passage of the needle appears almost impossible. After an entrance is effected the needle generally passes smoothly through the soft tissues, but only to encounter a new obstacle by coming in contact with the fascia. Some deep fascia are very tough and offer considerable resistance to the force of the operator, even with stiff steel needles.

Among those points may be mentioned—the cervical fascia, the thoracic fascia, particularly the ligamenta suspensoria, enveloping the mammary gland, the deep fascia under the pectoralis muscle, the fascia lata of the thigh, which is the thickest in the upper and outer side of the limb; the gluteal aponeurosis, investing the gluteus medius. At the linea aspera we find two strong inter-muscular septa. After the needle has overcome these obstacles it meets other dangerous anatomical points of vessels and nerves, through which it must be guided to its proper position before the electricity is allowed to work. The position of the working point of the needle must be in a place far enough from the cutaneous surface and the point of entrance, in order to avoid burning these parts, which would be followed by sloughing ulcers, leaving behind very ugly scars, as mementos. There are also tumors, some having on the outside a capsule, which resist an entrance of almost any force. Considering all these difficulties I have given my orders for a small platinum needle as follows:

The needle to be 3 inches long; size equal to a No. 6 French scale. The working point (non-insulated) three-eighths of an inch long. The point, spear shaped with as fine a point as possible, the widest part of the spear one sixteenth F. inch. The needle must be stiff enough to pass through tissues without bending. The blunt end of the needle non-insulated to be connected with cord by a binding screw. The whole needle well insulated, except at its extremities, as mentioned, smooth and even.

In order to make the platinum stiffer than in its natural state, iridium was incorporated into the platinum wire; of which only $2\frac{1}{2}$ per cent. can be taken up. Iridium is found as an alloy, sometimes with platinum; it is very hard and unmalleable. Its chemical equivalent is 99.

There were many failures by different instrument makers; but by persistence, and at last with the aid of Messrs. Geo. Tiemann & Co., of New York, I am able to exhibit now, a needle which is almost perfect. It is best to use platinum only for the working part of the needle, and to manufacture the shaft of steel. This gives more stiffness to the needle and therefore more direct force can be used to enter the tissues without bending or breaking. In the manufacture of the needle it is necessary to connect the two parts firmly together, and at last to make the insulation smooth, running even from point to shaft.

This needle has answered all practical purposes so far, but there is a possibility that a case may present itself having tissues which resist all efforts and force of the needle. In such a case I use first as a leader a strong steel director which is grooved, having a sharp broad point, both sides below the point are sharp and easily cut its way through the cuticle and fascia. This direc-

tor will pass anywhere and is pushed in the place where the platinum needle is desired to follow. Then the platinum needle follows the director in its groove and is pushed above to its place; the director is withdrawn and the electrolysis is made without any difficulty. The director passes direct and straight, making a smaller hole in the cuticle than an uncertain, bending needle would, and after withdrawal of the needle no opening could be seen after the operation.

With the improved platinum needle and, if necessary, the aid of the steel director, the electrolytic operations can be made with certainty, safety, and success.

THYROIDECTOMY.

Read by title in the Section of Surgery and Anatomy, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY JNO. B. DEEVER, M.D.,

PROFESSOR OF SURGERY PHILADELPHIA POLYCLINIC, DEMONSTRATOR OF ANATOMY AND LECTURER UPON SURGICAL ANATOMY UNIVERSITY OF PENNSYLVANIA, ATTENDING SURGEON TO THE GERMAN, ST. MARY'S, ST. AGNES AND PHILADELPHIA HOSPITALS.

In discussing the surgical treatment of goitre or bronchocele I propose to do it in a concise and practical way, basing my remarks largely upon the results of my own experience, and therefore will not deal with it from a statistical, theoretical or classical point of view.

Goitre or bronchocele is met with as one of three varieties: Fibrous, cystic, and pulsating or vascular. Bronchocele associated with exophthalmus not being, except in a few cases, amenable to surgical interference, I will not discuss. Of the fibrous and cystic varieties it is not uncommon to meet with these two conditions present in the same case, thus forming a fibro-cystic goitre. Secondary changes, such as the substitution of gelatinous colloid material for the albuminous, and calcification in the walls of the cysts, and in the fibrous tissue, may modify the variety or form of the goitre.

The surgical treatment of goitre embraces the following operative procedures: injection, electrolysis, incision and drainage, ligation of the thyroid arteries, division of the isthmus or middle lobe, myroidotomy, and removal. (Enucleation).

Indications.—In considering the indications for operative treatment, the character of the goitre matters but little, the latter having a much more important bearing upon the character of the treatment. The indications I will classify in the following manner, namely: Failure of the ordi-

nary treatment usually put into effect in these conditions, which embrace the class of remedies known as alteratives, used both internally and externally, the goitre persistently increasing in size, and causing any of the following symptoms:

1. Tracheal stridor.
2. Dyspnœa.
3. Dysphagia.
4. A rapidly growing goitre, particularly when in a downward direction.
5. Deformity occasioned by the presence of the tumor.

Tracheal stridor, a prominent and distressing symptom in many cases of large goitre, the result of pressure upon the inferior or recurrent laryngeal nerves, calls for reduction or removal of the growth. The former is practically feasible only when the growth is to a great extent cystic. If the growth be purely vascular, sudden suffocating dyspnœa may be brought about by fright; in fact, anything exciting the circulation, thus occasioning increase in size of the swelling, which by pressure upon the trachea, coupled with the contraction of the muscles which depress the hyoid bone and larynx, may cause almost immediate death. Tracheotomy under such circumstances would be anything but an easy operation. To illustrate the force of my remarks, and especially to the part the muscles may play, I cannot do better than refer to a case reported by Dr. Dewes in the *British Medical Journal* for 1879. The patient referred to was found by the Coventry police, apparently dying of suffocation; when on his admission to the hospital a large goitre was found, and a free median incision was made by M. Reed down to the tumor. The dyspnœa was immediately relieved. Upon the evening of the seventh day the dyspnœa returned, the tumor again enlarging, the patient dying in a few minutes. The autopsy showed that the posterior part of the tumor had broken down, allowing a large extravasation of blood which pressed upon the pneumogastric nerves. Here tracheotomy was out of the question, owing to the cervical portion of the trachea being entirely covered by the tumor.

Extravasation may take place suddenly into a goitre resulting in the formation of a large coagulum. Difficulty of deglutition may be caused by either unilateral or bilateral pressure upon the œsophagus, the symptoms thus occasioned simulating those of stricture.

Enlargement, if the tumor is increasing in a downward direction, is especially to be feared, and constitutes a strong indication for interference, as even tracheotomy, with the sole view of offering temporary relief, may be impossible, particularly if such a patient should be the subject of sudden dyspnœa.

Radical operative treatment in the case of a

goitre which has been subjected faithfully to both internal and external treatment with no effect, not causing any discomfort other than that of deformity would not, I dare say, be in accord with the opinions of the majority of surgeons.

I believe that if such a subject is of suitable age, in good general health, and when deformity of the neck is greatly objectionable, thyroidectomy is justifiable if the goitre is unilateral. Where the entire thyroid is involved, constituting a huge mass, I think it is better to make a complete division of the middle lobe (isthmus), having previously ligated upon either side of the point of the proposed incision.

In the case of singers suffering from a small goitre, where the enlargement has taken place in direction of the groove, between the trachea and the œsophagus, the site of the recurrent laryngeal nerves, and which does not yield to treatment, I am inclined to advise removal. The first evidence of nerve irritation is most likely to be huskiness of the voice, therefore here, as elsewhere, relief of pressure for fear of irremedial injury of the nerve or nerves suggests itself.

DIFFERENT OPERATIVE PROCEDURES.

I will speak of the different operative procedures in the order I have given them in the early part of the paper.

Injection.—The injection of any material with the idea of exciting inflammation short of producing suppuration is both a painful and likely to be prolonged procedure and is not certain to result in cure. One, too, which may be followed by suppuration. The injection of any material with the idea of exciting suppuration and consequent disintegration was, before the days of antiseptic surgery, probably the best treatment at our disposal. The position it holds to-day is a far different one. The first objection to be urged against it is its provoking suppuration. Suppuration in a structure like the thyroid gland, where absorption is so soon to follow with its train of septic symptoms, cannot be regarded as desirable. The injection of any astringent liquid into the parenchyma of a goitre is attended by some immediate risk: namely, that of a coagulum finding its way into the circulation and causing embolic obstruction. Electrolysis in certain purely fibrous goitres is unquestionably curative. (See Paper by Dr. Jas. Henric Lloyd, Trans. College of Phys., Philadelphia, 1890). Therefore in cases of this character coming to me for operation, and where the usual treatment, excepting electrolysis, has been given a fair trial, unless there are urgent symptoms demanding immediate and radical relief I advise treatment by the galvano-puncture before doing anything more radical.

I am one who believes that electricity has a place in surgery but, to be given properly, by which manner good results are to be obtained

alone, it must be given by one thoroughly familiar with the subject both practically and theoretically. It is not to be wondered at that so much is said against electricity as it is so often applied by those who know but little about its practical use. The requirements for one who uses the galvano-puncture, I should say, should be

1. Capability in the selection of the cases.
2. A complete knowledge of the subject.
3. Practical experience in its use.

In cystic and vascular goitres electrolysis is not only useless but may be harmful.

Injection and Drainage.—Injection and drainage, done of course antiseptically, where thyroidectomy is for any reason contra-indicated, offers in my judgment, the best treatment for goitres which are purely cystic, also those which are fibro-cystic and where the cystic element predominates; I believe the operation should be done with the patient anæsthetized and not with the use of cocaine. The goitre is to be exposed by a careful dissection, the cyst opened and the walls stitched to the integument. The cyst is now to be thoroughly irrigated with a solution of bichloride, a drainage tube introduced, the cyst cavity packed with iodoform gauze and dressed antiseptically. The details in carrying out antiseptics are to be adhered to most strictly.

In the fibro-cystic goitre where the cystic element is quite as prominent a feature as the fibrous, this treatment will be found in many instances to be followed by degeneration of the fibrous element.

Ligation of the Thyroid Arteries.—After a trial in the ligation of the superior and inferior thyroid arteries it is still an open question if much is gained by this treatment. Certainly in medium size goitres, particularly of the unilateral variety, the ligation of the thyroids is almost as much of an operation as removal, and one, I should say, quite as difficult. I can scarcely see the feasibility of this procedure, except perhaps when done in connection with division of the isthmus or middle lobe.

Thyroidotomy—Thyroidotomy division of the isthmus or middle lobe between ligatures, I believe to be advisable when the tumor is very large and involves the entire gland. The experience Mr. Sydney Jones (see *Lancet*, November, 1883), has had with this operation is, to my mind, quite sufficient to recommend it.

Excision of the thyroid gland, an old operation dating back to the time of Albucasis, has been and is at the present time regarded as a procedure attended by great risk, both so far as the immediate and the remote dangers are concerned.

The immediate dangers of the operation are shock, hæmorrhage and injury to the neuræd laryngeal nerves. The remote danger is regarded to be chiefly myxœdema. My experience with thyroidectomy has been confined to the re-

removal of unilateral goitre, in none of which cases has myxœdema followed. I must confess I would be apprehensive of this sequel in the removal of the entire thyroid. There is a wide difference of opinion among operators as to the proportion of cases in which it has been seen to follow complete thyroidectomy. That myxœdema will occur after complete removal of the thyroid gland there is absolutely no doubt. This has been proven both by recorded cases, also by the exhaustive experiments of Mr. Victor Horsly. I cannot feel other than that there are but few cases where the operation of complete removal of the thyroid gland would be justifiable, believing as I do that thyroidotomy would suffice. Certainly thyroidotomy should first be done, or at least attempted, when if this fails to offer relief, complete thyroidectomy may be entertained.

TECHNIQUE OF THE OPERATION.

The essential points to be observed in the removal of either a unilateral or bilateral goitre are

1. A clean exposure of the proper capsule of the tumor.
2. Not to open the capsule.
3. Securing the superior and inferior thyroid arteries between two ligatures close to their point of entering the gland.
4. The avoidance of injury to the recurrent laryngeal nerve both when exposing the inferior thyroid artery and in the separation of the growth posteriorly.
5. Tying the pedicle by transfixion with a strong aseptic silk ligature. If the dissection has been a clean one there is no occasion for the use of drainage. For closing the wound I prefer the continuous suture.

Case 1.—Miss A. V., aged 24, school teacher, was admitted to the surgical wards of the German Hospital, June 22, 1887, with a fibro cystic goitre involving the right lateral lobe of the thyroid gland.

The growth was the size of an average fist. She first noticed it six years previous—it has gradually increased in size and at the time of admission was giving her a great deal of trouble in swallowing, as well as paroxysms of dyspnoea. Superficial veins were much enlarged from pressure, growth was movable showing no evidence of adhesions. She was anæmic, otherwise her general health was good. For the past year it had troubled her so much that it was necessary for her to give up teaching, as talking for any length of time excited attacks of dyspnoea. Operation June 23. Growth found to be fibro cystic, which was easily removed. The wound healed rapidly and patient was discharged July 13, 1889.

Case 2.—F. L., aged 43. Laborer. Large fibro cyst in goitre of right lobe of thyroid, began to form twelve years ago. At the time of

admission to the hospital patient was suffering with dysphagia and dyspnoea. Growth was dissected out. Many vessels were tied with catgut. Union by first intention; patient made a good recovery.

Case 3.—Miss A., age—. American. Occupation, teacher in a convent; came under my observation in the summer of 1890, presenting a tumor of the left side of the neck extending from the angle of the jaw above, to the clavicle below, inwards to beyond the median line of the neck and posteriorly to beyond the outer edge of the sterno-mastoid muscle and riding over the large vessels. The middle of the anterior surface of the tumor presented a depressed cicatrix. This growth had been present for several years. Two years ago it was much larger than now; when it was capped a quantity of clear fluid drawn off, and the sac injected with a tincture of iodine. The size of the growth was diminished by the tapping, but not entirely removed. Prolonged suppuration followed the tapping, ending finally in the obliteration of the sac. The growth, which was fibro-cystic in character, now became fibrous as a result of the elimination of the cystic element. My diagnosis was a fibrous goitre involving the isthmus and the left lateral lobe of the thyroid gland. The patient was prompted to seek further relief for the following reasons:

1. On account of chronic hoarseness which at times amounted almost to aphonia.
2. On account of the growth increasing slowly in size.
3. On account of discomfort in both breathing and swallowing.
4. On account of the deformity of the neck.

I suggested a trial of electrolysis before having the operation of thyroidectomy, feeling that the latter operation would be a more difficult one in the present case than ordinarily, owing to the inflammatory process set up by the iodine. The patient was referred to Dr. James Henric Lloyd, who made 15 punctures with the galvano-cautery with a positively negative result. There was left but one course now to pursue, that of the removal of the growth, which I advised and to which the patient agreed. Accordingly, January 29th, 1891, with the patient under ether, after a careful, tedious and long dissection, I removed the growth. There were many vessels to contend with, but by far the most troublesome part of the operation, was the attempt to separate the internal jugular vein, owing to its being adherent to the capsule of the goitre. In this attempt the vein was torn at three points. The bleeding was arrested by the application of hæmostatic forceps which were allowed to remain for 72 hours. The pedicle, as well as the blood vessels, were tied with aseptic silk. Following the operation, there was difficulty in swallowing, which was attributed to the manipulation of the œsophagus necessitated

by the separation of the growth. An irritated cough and high pulse rate (ranging from 140-160), persisted for three days. This I believe was due to nerve irritation, consequent upon the operation.

Case 4.—E. F. C., 64 years, American. Occupation, farmer. A tumor in the anterior portion of the neck was first discovered by the patient about twenty years ago, during which time its growth has been slow. For the past year its growth was rapid, especially since last summer. It never produced any symptoms other than marked difficulty in breathing. For the past year the patient has not been able to sleep on his back or right side. He was admitted to the German Hospital, March 23, 1891. The tumor, the size of a large foetal head, occupied the anterior or left lateral region of the neck, extending from the angle of the jaw to two inches below the clavicle. There was laryngeal stridor with aphoned and painful paroxysmal of dyspnoea. A diagnosis of cystic goitre was made. Owing to the advanced age of patient, and his general condition, by no means favorable for enucleation, I decided to open and drain. His dyspnoea was so severe it was not advisable to give an anæsthetic until the tumor was aspirated, thus relieving the pressure symptoms. This was done the following day and I drew off a semi-gelatinous fluid tinged with blood. Ether was then given and cyst was opened, and its walls stitched to the skin. This was followed by considerable hæmorrhage which required the packing of the sac with iodoform gauze around the drainage tubes. After this the growth was reduced to the size of an ordinary fist. The patient progressed slowly, with a temperature fluctuating between 99 and 102°. The pressure symptoms were relieved completely. He is still under observation and now the tumor is the size of a hen's egg and there is a sinuous track occupying the seat of the drainage tube. The tumor occupied the anterior and left lateral region of neck. A diagnosis of cystic goitre was made: owing to the advanced age of patient, and his general condition, by no means favorable for enucleation, I declined to open and drain the cyst, which was done the following day. I first operated and drew off a semi-gelatinous fluid tinged with blood. I then opened the cyst and stitched the walls to skin. This was followed by considerable hæmorrhage, which necessitated the packing of gauze around the drainage tube.

ACETANILIDE is now being used in lieu of iodoform in some hospital practice in the form of a fine powder on some kinds of sores.

DR. E. S. ELDER, of Indianapolis, was elected president of the Mitchell District Medical Society at its recent meeting at West Baden.

CÆLIOTOMY (ABDOMINAL SECTION) FOR RUPTURE OF THE PARTURI- ENT UTERUS.

Read by Title in the Section of Surgery and Anatomy, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY HENRY C. COE, M.D.,
OF NEW YORK.

Introduction.—Although the literature of this subject is quite exhaustive, most authors deal with the etiology and pathology of rupture of the uterus, rather than with the treatment, and much of the teaching with regard to the latter antedates the era of modern abdominal surgery. The writer feels some hesitation in writing upon this theme, as it has been already ably presented to the American Medical Association by Dr. Wm. H. Walker and Dr. C. A. R. Reed, in papers read before the Obstetric Section. The writer's purpose in reintroducing the subject before the Surgical Section is to have it discussed from the broad standpoint of *general surgery*. This is entirely proper, since rupture of the uterus is to be considered in the same light as rupture or other lesions of any other of the abdominal viscera. It is preëminently a *surgical emergency*, and should not be studied from its gynecological (or obstetrical) side alone. When Lawson Tait feels justified in proposing Porro's operation as the proper treatment for placenta prævia, we may well ask: "Is simple expectant treatment applicable to the far more formidable obstetrical complication, rupture of the uterus?" Note that the paper deals with rupture of the *parturient* uterus, and not with injuries of the organ before labor. This is an important distinction, to be borne in mind in the discussion.

The writer bases his paper entirely upon his personal experience—that of four cases (seen within a period of eighteen months) in which abdominal section was performed. One case was successful, the patient being now in perfect health.

Brief outline of cases:

Case 1 (reported in *extenso* in *New York Med. Record*).—Rupture due to undue interference in the first stage (forceps and attempted version), the child being of unusual size. Operation two hours after the accident, the patient being in collapse from active internal hæmorrhage. The child's head had escaped from the rent, which extended from the cervix through the left broad ligament, half way to the fundus. Child extracted through the rent, after application of rubber cord. Uterus removed and pedicle treated by the extra-peritoneal method. On account of extensive laceration, the entire stump sloughed out, but the patient made a good recovery.

Case 2.—Cause of lesion identical with that in *Case 1*. Injury not recognized until twenty-four hours after the birth of the child, when the patient was already septic. Cœliotomy. Trans-

verse tear on posterior aspect, 4 inches long, in lower segment, with commencing peritonitis. Rent sutured, and thorough irrigation and drainage. Death from shock twelve hours later.

Case 3.—Moderate contraction of anterior conjugate, with large child. High forceps unsuccessful. Delivery after difficult version. In removing an adherent placenta the accoucheur withdrew a coil of small intestine, which prolapsed through a rent in the posterior wall of the uterus. It was replaced (as was supposed), and the opening was plugged with iodoform gauze. Abdominal section was then regarded as unjustifiable, on account of profound collapse. The writer saw the patient eighteen hours later, found her in fair condition, the upper portion of the vagina being filled with intestine. He proposed and performed cœliotomy at once. There was a transverse tear posteriorly in the lower segment, extending between the bases of the broad ligaments. It was too extensive to suture, so both broad ligaments were clamped, and the uterus was extirpated *in toto* in five minutes. It was found that the intestine had not been replaced, but had been nipped by the edges of the rent, so that at least 3 feet were black and gangrenous. Irrigation and gauze drainage per vaginam. Death from shock ten hours later.

[The above were private cases.]

Case 4 (Maternity Hospital).—Spontaneous rupture during normal labor, not recognized. Collapse five hours later, but no extensive hæmorrhage. The writer saw the patient twelve hours after the accident, and diagnosed rupture of the uterus with internal bleeding. A consultation of the attending staff was held, and the unanimous opinion was that there was an extensive laceration into the left broad ligament, and that active hæmorrhage was in progress, which it was necessary to arrest. There was doubt as to whether the rent extended into the peritoneal cavity or not. Exploration advised. This was conducted rapidly. No blood found in the abdominal or pelvic cavity. There was an immense hæmatoma of the left broad ligament, extending upward into the corresponding iliac fossa. Abdominal wound closed and vagina tamponed with gauze, although *there had not been any external hæmorrhage whatever*. Death from shock.

Here follow extended references to the literature of the subject, from which and the cases reported are drawn the following inferences:

Many cases of spontaneous rupture are doubtless unrecognized by the general practitioner. Profound shock after delivery should always awaken suspicion, even if there is only moderate external hæmorrhage, and a thorough examination should be made. Text-books give rules for recognizing rupture only *during* parturition.

The rules laid down for the treatment of rupture are uncertain and confusing. The tendency

of the practitioner is toward purely expectant treatment. He would pack the vagina with gauze and wait. This course is too often fatal. The emergency is a *surgical* one, and is to be treated according to the ordinary rules of surgery.

The fact that successful cases of cœliotomy for rupture of the parturient uterus are comparatively rare, is no more an argument against the operation, than if it was applied to gunshot wounds of the abdominal viscera. In analyzing the unsuccessful cases, it will generally be found that operative interference came *too late*, *i. e.*, from eight to eighteen hours after rupture. The writer's successful case was as unfavorable as could be imagined, but the patient was operated upon promptly, as soon as the lesion was discovered. Two methods of active treatment are now recognized and practiced, *viz.*: 1. Drainage per vaginam. 2. Abdominal section, followed by either, *a*, drainage; *b*, section of the tear; or *c*, amputation of uterus. Simple drainage has some powerful supporters (mainly in the Vienna school), and the statistics are apparently convincing, but it is not capable of general application to all cases, and the indications are not always clear, because without opening the abdomen it is frequently impossible to determine the following important points: 1. The nature and extent of the tear; 2. The presence of active hæmorrhage; 3. The presence of blood and amniotic fluid in the peritoneal cavity. [It is assumed that the uterus has been emptied.] The writer thinks that abdominal section is indicated under the following conditions:

I. Before the uterus is emptied.

1. When the placenta or *any* portion of the foetus has escaped from the rent. Attempts at manual delivery only increase existing shock and destroy the patient's chances after section, as invariably shown by records of unsuccessful cases.

2. When there is evidence of progressive internal hæmorrhage.

II. After the uterus is emptied.

1. When there is extensive prolapse of the gut through the tear (as in Case 3).

2. In all complete lacerations (especially in those involving the broad ligaments), except small tears low down, near the vaginal fornix (as in Case 2), where good drainage can be maintained.

3. In incomplete tears in which the broad ligament is extensively involved (as in Case 4), and there is evidence of progressive hæmorrhage. [This point must remain *sub judice*. Only one other beside the writer (Peters) has opened the abdomen in such a case. His patient died, and the report of the case provoked considerable adverse criticism. In the discussion before the Vienna Obstetrical Society, only Gustav Braun expressed the opinion that section was justifiable when there was no evidence of progressive inter-

nal bleeding, and it was not certain whether the tear was complete or not.] Parvin's summary is a comprehensive one, viz.:

"Probably the solution of the question is this, that where the tear is in such a position that vaginal drainage is perfect, the abdomen need not be opened; but if such drainage is impossible, or imperfect, then section is indicated."

What shall we do after opening the abdomen?

1. Arrest hæmorrhage, either with forceps or the temporary rubber ligature.

2. If the tear is small (2 inches), and is low down in Douglas' pouch, drainage per vaginam may be indicated.

3. If the tear is clean-cut, without contusion of the edges, and does not involve the cervix or broad ligaments, it may be closed with deep and subserous sutures.

4. If the tear is not low down, is extensive, with contusion of the edges, and especially if a portion of the fœtus protrudes, amputation of the uterus, with extra-peritoneal treatment of the stump, is indicated. (The child can be extracted through the rent before removal of the uterus (Prévat) or afterwards (Porro).

5. In extensive transverse tears in the lower segment (as in Case 3), and in tears beginning in the cervix and extending upwards through the broad ligament, the writer would strongly urge the propriety of total extirpation of the uterus as the operation *par excellence* (as it is in many cases of hysteromyomectomy), for the following reasons:

1. It requires less time than Porro's operation, and is quite as easy, especially if the patient is placed in Trendelenburg's position. There should be no greater shock or loss of blood.

2. All the contused tissue is removed, which if left behind in the stump, will inevitably slough and imperil the life of the patient (as in Case 1).

3. Drainage is perfect. After thorough irrigation and toilet of the peritoneal cavity, it can be closed, drainage being maintained per vaginam with iodoform gauze, as after vaginal hysterectomy.

Conclusion.—The writer deprecates any intention of recommending a heroic method of treatment to the entire exclusion of the more conservative. He is an avowed conservative in abdominal surgery, but believes that rupture of the parturient uterus is a desperate emergency, in which a fatal issue is the rule, and that it requires prompt and energetic treatment according to the rules of modern surgery. The fact that the statistics of cœliotomy in these cases have shown a large mortality, is not an argument against the operation. In every case the accoucheur, if not himself a surgeon, should without an instant's delay summon experienced counsel, and explain to the family that immediate resort to abdominal section may be necessary. Only by prompt interference

can we improve statistics, and thus elevate the operation above the level of a hopeless and, apparently, unnecessary surgical experiment.

SOME POINTS IN THE SURGICAL TREATMENT FOR THE RADICAL CURE OF HERNIA.

Read in the Section on Surgery and Anatomy, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY AUGUSTUS P. CLARKE, A.M., M.D.,
OF CAMBRIDGE, MASS.

One of the most important features in the surgical treatment for the radical cure of hernia is the selection of the proper material for sutures. The sutures in all cases should be aseptic. The wound made by the incision should also be kept aseptic. The operator should have knowledge of the manner in which the sutures have been made, and in order to have such knowledge he should superintend their final preparation. Sutures which have been prepared and are sold in shops should in no event be trusted, notwithstanding the careful manner in which they may seem to have been prepared. No one, except the surgeon, or his immediate assistants who are to use them, and who have taken occasion to make most careful observation, is at all likely to appreciate this necessity, and to carry out in every detail measures necessary for assuring their preparation in such a manner that they can be relied upon as being surgically clean and perfectly free from germs. Experience has demonstrated that the best material for buried sutures is that obtained solely from animal substance. Catgut and tendon when properly prepared afford the best material as is yet known for such sutures. Considerable experience is required in chromicising them. If the sutures remain long in the acid they become hard and offer too much resistance to the action of the tissues. The same effect occurs when the quantity of acid is in excess of the due proportion. If, on the contrary, the sutures are not sufficiently chromicised they undergo absorption before complete union of the coapted parts of the wound takes place. Silk ligatures, however carefully prepared, should not, as a rule, be employed in operations on hernia; their substance is not akin to those of the tissues into which they are to be inserted; they are liable to be the medium either directly or remotely of sepsis, and are rarely, if ever, absorbed. In cases in which they have been used, it has been necessary, for the most part, to establish some means of drainage. Such expedients serve to prevent the occurrence of immediate adhesion of the tissues, and to render the line of union weak and yielding, and consequently to afford but little protection against a return of the hernia. The

same may be said when horse hair and certain other materials are used for such sutures. It is true that for affording immunity against the recurrence of the hernia, the internal ring may be embossed by the inverting of the sac on its peritoneal surface. This measure may, for the time being, be of some service, especially in a case in which a well fitted truss is worn. Such unnatural coaptation of parts is liable, however, to yield before the super-incumbent pressure of the abdominal viscera and thus to cause a return at length of the hernia. Application of quilled sutures falls far short of accomplishing what is most to be desired, for the adoption of this method of procedure, when silk, or like substances are employed, has to be supplemented by some special provision for drainage to the wound. One of the features which I here insist upon to be achieved is that the several different tissues be coapted, each in its proper order and that direct and immediate union be secured without the necessity of having to resort to any method of drainage whatever. Another important feature to be secured in the operation is the restoration of the obliquity or the valve-like form of the inguinal canal, and also of the internal and external abdominal rings. Attention has been called to the importance of this measure, but as yet, I believe, it has not been generally appreciated. This may be effected by free dissection proceeding from the internal ring. In cases in which the tissues have undergone serious changes, or the parts have become distended, deformed, thickened or attenuated, much difficulty will be encountered in accomplishing such restoration. Every effort, however, should be made to bring back the canal as near as possible to the typical one, as regards length, diameter and obliquity. In those cases in which the canal has become tortuous, or in which the opening is formed at an undue angle to the parietes of the abdomen, and the parts are not reformed, but are left in abnormal condition, the operation undertaken for the radical cure will prove to be of temporary benefit only. Statistics are sometimes offered by different operators to show that certain methods of practice are attended with unusual success. Statistics can be of but little value when the individual operators select cases with the view of showing favorable results of their special methods of operating. In a case in which the sac is to be removed the cord should be freed as high as possible even if the peritoneum has to be impinged upon. The sac should be sewed off by means of aseptic animal sutures; and if the other steps in the operation have been properly taken there will be scarcely any danger of a return of the hernia. There are several advantages in the method of removing the sac. Prominent among them is the greater facility for inspecting its contents and for guarding against the possibility of reducing parts

which may be in a state of inflammation. Such a condition of the parts is particularly apt to occur in cases of strangulated hernia, after prolonged taxis or other measures for relief have been undertaken. When the hernia has been properly reduced, the sac should be regarded only as an unnecessary incumbrance. The sac is formed originally from the parietal peritoneum, which frequently becomes distended and thickened. The various changes in its nutrition and vascularity often lead to irritation, inflammation and adhesion, according to circumstances and accidental conditions. In all cases, after opening the sac the surgeon should see whether the circulation returns. If the parts have been too long compressed and there is much danger of sloughing it will be advisable to resort to resection of the necrosed portions and not to assume risks of returning them. After opening the sac and relieving the constriction, and before making reduction, the contents of the sac should be carefully examined. If there is evidence of inflammation or an effusion of lymph, free irrigation with mercuric bichloride should be had recourse to. The sac should then be sewed across at its neck with animal suture, and be excised. Different methods of operating for the radical cure of hernia from time to time have been reported. Emphasis is often laid upon the adoption of the most careful antiseptic precautions. A more particular examination of such reports almost invariably reveals the fact that some method of drainage has been employed. Among the methods observed is the one in which the horse-hair drain left in the canal, or "gauze plugs" connected with the wound; and that the wound united by "granulations from the bottom." The failure on the part of the operator to keep the wound aseptic must necessarily render the line of union weak, the parts in large measure devoid of vitality, and thus incapable of overcoming the pressure which is the cause of the recurrence of the hernia. This is the reason no doubt why so many different methods for the radical cure of hernia have been devised and why each method of operating, for the most part undertaken by a different surgeon, so often proves unsatisfactory. In some cases of femoral hernia excision of the sac is almost imperatively demanded. In those cases in which Macewen's method is adopted the thickened mass is liable to set up more or less irritation, and to become the source of much inconvenience.

When the sac is removed the ring and canal can be narrowed, and sutures can be introduced in close proximity to the vessels without causing injury or disturbance to the circulation. Another advantage, according to Mr. Poland,¹ is that it allows the closure of the neck of the sac, and thus effectually prevents all hæmorrhage from the wound into the peritoneal cavity. After the sac

¹ John Poland, F. R. C. S., Braithwaites Ret., Part 98, page 124.

has been removed the loose folds in the vicinity can be more nearly approximated; the exudation of plastic lymph readily closes the wound effectually from any communication with the abdominal cavity. After the edges of the pillars have been refreshed they may be brought together, and retained by aseptic sutures. By this means the canal is reformed but narrowed, and becomes an effectual barrier against the recurrence of hernia. This method is evidently of far more importance than the one which seeks to utilize the sac by invaginating it in the canal and by converting it into a pad or fixing it as a boss over the internal ring. Of course, in cases of chronic hernia, in which there has been much inflammation, considerable difficulty will be experienced in separating the sac from the surrounding parts. If, however, much care be exercised, and a liberal use of the aseptic sutures be resorted to, the sac can be separated and be removed, to a certain extent, without incurring the risks of gangrene, suppuration or inflammation, and the operation will therefore not appear so difficult or dangerous as some writers would lead us to believe. In a recent case in which the hernia is quite small, the sac and hernia may have passed into the abdomen and so have disappeared. These cases may be operated upon without our interfering with the sac. The edges of the pillars should in such cases be refreshed, and approximated by aseptic animal sutures. The other parts are sewed together according to the method already referred to. In congenital cases the cord and sac are frequently found so blended with each other that to separate the one from the other is often most difficult and tedious. In such cases, when there is no appearance of recent lymph, portions of the sac may be left. The remaining fibres, for the most part, usually undergo absorption or degeneration. This measure in the operation is quite different from the one which, as said before, seeks to plug the canal and internal ring by means of the retained or inverted sac that is liable to form a painful or hardened mass in connection with the ring and canal. In operations for the cure of hernia the use of wire sutures is unnecessary, and should not be encouraged. The use of wire sooner or later becomes the source of inconvenience, if not of serious trouble, and notwithstanding the efforts made in other respects to keep the wound aseptic, their presence is followed by irritation or ulceration, conditions that will necessitate their early removal, and thus compromise the usefulness and advantages that should be derived from the surgical measures undertaken. Other methods of treating the sac have been proposed. The cases in which the method by torsion of the sac can with any degree of safety be resorted to are too few for general considerations. In every such case the operator of course must be a law unto himself. In

conclusion I would say that every operation, for the radical cure of hernia, in which the wound is kept strictly aseptic, including the employment of thoroughly aseptic animal sutures, the results will be most satisfactory, and but little danger is to be apprehended of a return of the hernia. These favorable results may be expected to follow in the cases in which the sac has, as far as possible, been excised, without injury to the cord or other parts. In all cases expected to be successful the operation should be so conducted that no drainage, however simple in its details, should in any way be required. The necessity of observing this principle in operations for the cure of hernia has been urged by my friend, Dr. H. O. Marcy.² He says the "Coapted surfaces held aseptically at rest, readily tolerate the limited effusion which is utilized in the process of repair. The elimination of the drainage-tube renders the complete closure of an aseptic wound possible, and prevents its further extraneous contamination. Repair ensues as in a subcutaneous wound. The advantages of this method in the treatment of the wound is the assurance of non-infection. By every method of antiseptic dressing with drainage all surgeons have admitted the great difficulty, and, in children, the well nigh impossibility of retaining the wound aseptic." The results of the operations in the hernia cases occurring in Dr. Marcy's practice with which I have been connected, and also in those in my own for the past twenty years, fully justify the conclusion here reached. By the observance of these principles of asepsis in operative treatment for the radical cure of hernia, Dr. Marcy has, according to my judgment, attained a success that has scarcely been paralleled.

ARISTOL: SOME OF ITS USES IN SURGERY.

Read in the Section of Surgery and Anatomy, at the Forty-second Annual Meeting of the American Medical Association, at Washington, D. C., May, 1891.

BY WILLIAM C. WILE, A.M., M.D.,
OF DANBURY, CONN.

My attention was first called to the value of aristol in the treatment of surgical cases, by Dr. Eichhoff, of Elberfeld, Germany, and Lowenstein, of Vienna, whose reports were published in the early part of 1890. I have always been a firm advocate of the value of iodoform in surgery, but I had become well convinced of the fact that it was, in many cases, a source of great annoyance, from its repulsive odor, to a great majority of cases, and having seen many, where its poisonous effects were apparent, I at once became impressed with the value which must pertain to a remedy which was free from toxic effects, was inodorous and as valuable an antiseptic as iodo-

² Treatise on the Radical Cure of Hernia, page 87.

form. One of the very first cases in which I used it was of such a character, and the results were so satisfactory, that it almost immediately displaced iodoform in my practice, and from that day to this I have used aristol entirely when it was at hand and available.

Dr. Hobart Armory Hare, says: Experimental and practical clinical experience have shown that it can be used in all instances where iodoform can be applied externally, and it is said to possess the advantage of being almost entirely harmless to man, although it is a powerful parasiticide.

Dr. C. W. Allen, New York, in a paper read before the American Dermatological Association, gave the results of his experience with aristol, and summed up with the statement that it seemed to possess valuable cicatrizing, granulating and stimulating qualities, was void of the objectionable odor of iodoform.

Dr. Alois Pollak has employed aristol as an antiseptic in twenty-two cases of unhealthy wounds, abscesses, minor surgical operations (such as removal of small tumors or enlarged glands), phlegmonous inflammations and varicose ulcers, and is enthusiastic in praise. He used the drug in the form of a powder, or mixed with ether or vaseline. In all of the cases in which it was employed there was no reaction; and fever, if present, disappeared within twenty-four hours. No pain was experienced in or around the wound, and healthy granulations were rapidly formed. The author regards aristol as an excellent substitute for iodoform; its advantages being that it has no disagreeable odor, is effective in much smaller quantities, and a thin layer of the powder is sufficient to cover the wound.

Dr. Boufill calls attention to the great value of the drug in burns; a 10 per cent. salve of aristol proving eminently efficacious.

Dr. F. Goldmann mentions the use of aristol in speaking of the frequency of burns received during laboratory work; these are sometimes of a peculiarly severe type, but a 5 or 10 per cent. salve with lanoline effected a painless and comparatively quick cure, almost invariably.

Dr. Robert T. Morris, of New York City, after testing aristol in the hospital of the New York Presbyterian Graduate School, says: "It seems after a careful series of experiments that it is superior to iodoform in all classes of surgical cases, in which the former was applied," and Dr. Manley, of the same city, in an article published in the *New England Medical Monthly*, takes about the same ground. The case referred to was that of a little boy, Tommy H., aged 9 years, who had met with a frightful laceration of the left leg. He was with a mate playing on a flat car in the yard of the Housatonic R. R. Co., in the city of Danbury. The car was isolated

on a side track, and the boys were running and jumping on and off, dancing on the platform and the like. After a while they tired of their exercise, and seated themselves on the end of the car with their feet hanging over it. Without warning and without being seen by the employes, a car loaded with lumber was backed up to the side track. This car was loaded with loose lumber and over the front the irregular ends protruded. Before the boys realized their danger the car was upon them, and some of the projecting boards caught Tommy's leg. It was almost immediately released, and the injured boy taken to his home while I was sent for. On my arrival I found on a superficial examination that his injury was a very severe one, and that it was advisable to have him taken to the hospital, especially as his home was a poor one, which was done. On arrival at the hospital, he was given ether and a careful examination was made, with the following result. It was found that almost all of the soft parts of the leg were fearfully lacerated, and that the tibia had sustained a transverse fracture. It did not seem that it would be possible that his leg could be saved, but remembering that children have wonderful recuperative as well as reparative power, I determined to make the effort. All of the macerated tissue was carefully dissected, trimmed away, and the wound carefully cleansed. Then the torn ends of the muscles were coaptated as well as possible, the tendons united, and the integument replaced as much as was possible. Of course all of this took a long time, and was done with full antiseptic precautions, and the suturing was made with catgut. The integument was so badly torn and lacerated in some places that it had to be trimmed, and there were some bare spaces. The whole of them was covered with a heavy coating of aristol, enveloped in antiseptic cotton, and put up in a plaster of Paris bandage, setting the fractured bone at this time. This dressing was not removed for one week. There was no elevation of temperature, and the boy required very little anodyne to keep him quiet.

On the removal of the dressing at this time it was found that a most wonderful metamorphosis had taken place. Union had been established over a considerable extent of the integument, and all of the tissues beneath seemed to have united firmly. There was simply no odor to the wound, and quite firm bony union had taken place. Over the spaces which were denuded of the integument healthy granulations were springing up all over, and the prospect was very bright for saving the limb. It was washed off carefully with bichloride solution, one to two thousand, aristol freely dusted on, and plaster of Paris again applied as before, leaving windows for the purpose of frequent dressing of the denuded parts. This was left on for one week more, when it was found

that union in the bone was so firm that the plaster of Paris splint need not be further used. It was dressed as before, and this treatment continued for another week when all was perfectly healed, and in four weeks from the time of his entrance into the hospital he was discharged cured. When we take into consideration the extent of the injury to the soft parts, I am sure that you will agree with me that this result so readily attained was little short of the marvellous.

The next most gratifying case in which I used it was that of James A., who was suffering from a very large specific bubo which was gangreneous in its character. He had been under the charge of several physicians, and his life seemed to hang by a single thread. The cavity was well washed with Marshland's peroxide of hydrogen and packed with aristol. This was renewed every day and the bubo not only rapidly healed, but the general condition of the patient immediately improved. All the internal medication I gave was a dessert-spoonful, three times a day, of the elixir of three chlorides, and a generous diet.

I have used it in varicose ulcers of the leg with the most charming results. In this troublesome affection I firmly believe that no other treatment will bring about such gratifying results as aristol and the rubber bandage. Its effect is immediate and rapid.

A little girl was horribly burned on both legs from her clothes catching afire. The fire was quickly extinguished, but the burns on the limbs were very severe, extending to the second degree. I made an ointment of aristol one drachm to lanolin one ounce and a half, and spread it thickly over the whole inflamed surface. The limbs were then put up in absorbent cotton, and roller bandage, which was not taken off for one week, when it was found that the whole surface had healed, except two places the size of hen's egg, which subsequently healed under a few dressings. I have used it in five other cases of this character with equally good effect.

In recent wounds resulting from traumatism of any character it is probably seen at its best. Its action is peculiar. Take a given wound which has been carefully cleaned by antiseptic methods, stitched together, and aristol dusted on the surface; when the next dressing is made the following will be observed: There has been no exudation. The aristol is as dry as when it was first put on. The wound is also as dry, or even dryer, for where there was a particle of moisture the aristol had sealed it in, as it were; and the wound had healed while perfectly dry. I have never seen a case of injury which was treated by aristol that did not heal perfectly and entirely, provided I had been careful to make it perfectly aseptic prior to its application. In conclusion, aristol has many advantages over iodoform, inasmuch that it is perfectly non-poisonous,

has no odor, does not irritate, is fully as good an antiseptic as iodoform, and in our opinion the ideal one.

LINEAR CRANIOTOMY (MISCALLED CRANIECTOMY) FOR MICROCEPHALUS.

Read in the Section of Surgery and Anatomy, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY W. W. KEEN, M.D.,

PROFESSOR OF THE PRINCIPLES OF SURGERY, JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

I have entitled this paper "Linear Craniotomy" instead of "Craniectomy," the word proposed by Lannelongue and formerly used by myself. The operation is practically a long incision in the skull, the removal of a part of the bone being merely incidental to its being a hard instead of a soft tissue. The termination "ectomy" usually and of right signifies the entire removal of the part preceding this termination, *e. g.*, oöphorectomy, omphalectomy, nephrectomy, etc. Removal of the cranium (as craniectomy means) being scarcely intended or done, our nomenclature should fit the facts. Dr. Bauer uses the word craniotomy in reference to his case (see below), but trephining is, I think, the proper one to describe his operation.

In *The Medical News* of November 29, 1890, I published a case of linear craniotomy for microcephalus. The object of the present paper is to report the later history of this case and two additional cases that I have had, as well as brief notes of one kindly furnished me by Drs. B. Sachs and A. G. Gerster, of New York, and another similar furnished me by Dr. J. C. McClintock, Professor of Surgery in the Kansas Medical College, making with Lannelongue's two cases and Wyeth's case, eight in all that have been done so far, and to refer to two other cases done before my own, for the same disorder and with the same intention, but by methods which I cannot think should be classed as craniectomies.

Case 1.—(For earlier history see *The Medical News*, November 29, 1890.) Since the operation this child has certainly improved steadily and considerably, but not at all to the extent of the case reported by Lannelongue. She screams almost none at all, sleeps better, notices a watch when held before her, observes things about her, and has used a number of words, occasionally but not constantly. She drools and screams but little and has almost lost the restless wringing of the hands which was so marked a peculiarity before the operation.

February 17, 1891. A precisely similar operation to the first was done upon this patient at the Jefferson Hospital. The improved forceps enabled me to do it in thirty-five minutes instead

of an hour and a quarter. She was entirely well in five days. No drainage was used.

March 24. The child is slowly improving. I do not see that her progress has been any greater since the second operation than before.

Case 2.—K. K., girl. Patient of Dr. F. X. Dercum.

Condition, May 23, 1890.—Age 1 year (when first brought to Dr. S. Weir Mitchell at the Orthopædic Hospital and Infirmary for Nervous Diseases). Very small. Makes no attempt to walk or sit; moves arms well; feet and hands cold; muscles flabby. Circumference of head $14\frac{1}{4}$ inches; diameter, biparietal, 4 inches; occipito-frontal, 4.5 inches. Knee-jerk slight, sensation good, no clonus, no rigidity. Fontanelle closed. Nose-bridge very wide. No mental development; hearing and vision good; does not speak at all; disposition good. Passes water and stools without notice. Spine straight. Five teeth. A general restlessness comes on at times; usually excessively cheerful.

Both parents alive and well. Father and mother are first cousins. No venereal history; no consumption in the family history except a sister of the father who contracted consumption. The mother has been married five years and has two children, of which the patient is the younger. Her brother is 4 years of age, and is strong. He was breast-fed; is hydrocephalic; circumference of head 53.3 cm.

The patient was born at term. Labor lasted twenty four hours and was very hard. No instruments were used. Patient was very small in size. No palsy, but very weak. No fontanelle existed at birth and her head has not grown since, though her body has. She was breast-fed for three months, and since then bottle-fed. She had a cold in her head for six months.

Condition, December 1—Nineteen months of age. Cannot sit alone; constantly in motion; 12 teeth. Circumference of head 36 cm. ($14\frac{1}{4}$ in.). Biparietal, 10.3 cm. ($4\frac{1}{8}$ in.); biauricular, 10.2 cm.; bitemporal, 8.3 cm. ($3\frac{1}{2}$ in.); occipito frontal, 11.9 cm. ($4\frac{3}{4}$ in.). Circumference of chest, 38.2 cm. ($15\frac{1}{8}$ in.). Height, 69.8 cm. (27.5 in.). Weight 12.5 pounds. [I append the following normal measurements at birth from Schröder's *Lehrbuch der Geburtshülfe*: Length 50 cm. Head, bitemporal, 8 cm.; biparietal, 9.25; occipito-frontal, 11.75 cm.; circumference, 34.5 cm.] Top of head quite prominent. Can hold things in her hand; cannot feed herself. Moderate contraction of flexors of both feet; legs not paralyzed, knee jerk absent, no ankle clonus. In repose idiotic expression. Frontal lobe re-treating. Two convulsions this summer, two last winter, each time with teeth. Has the expression of a precocious idiot. Attention can be won, but only momentarily. Mind and eye flit from one thing to another quickly.

Opération at the Infirmary December 3, 1890.—An incision was made one inch to the left of the middle line, parallel to the sagittal suture and six inches in length. A curved incision was then made from the anterior end of this line downward so as to lift a frontal flap, the scar of which would be hidden by the hair. A half-inch button of bone was removed by the trephine, and from this anteriorly and posteriorly a furrow a quarter of an inch wide was cut out of the bone, extending to within an inch of the supra-orbital ridge and an inch above and to the left of theinion. The length of the furrow was five inches.

The amount of hæmorrhage from the scalp was very slight, much less than I have found it in adults. The bone was very thin, about one to one and a half mm. only, but bled freely. Opposite the parietal boss the dura was very adherent to the bone, but at all other points was separated easily. When the point of a pair of scissors was put under the flap of bone, thus loosened and the handle of the scissors let down gently, the simple weight lifted the flap perceptibly. The periosteum corresponding to the bone removed was cut away. The dura had not been opened, and appeared normal.

A few strands of horsehair were placed in the furrow and the wound dressed. The operation lasted half an hour. Temp. at its close 98° .

13th, (10th day). The wound healed kindly and quickly, and in five days the stitches were out. During the process of healing the child showed unusual fluctuations of temperature, the highest being, however, only 100.8 , for which no apparent cause could be found. After keeping the child a few days longer in the hospital to be sure of a safe recovery she was sent home to day. The attendants at the hospital are decidedly of the opinion that she is quieter and calms at her head much less than she did before the operation, though for myself I can scarcely see much difference.

March 2, 1891. The child has improved very much in general mental condition, but not so rapidly as I could wish. Accordingly, to-day I did a linear craniotomy on the other side of the head in precisely the same manner as the former operation. The operation was wholly completed in twenty minutes by the new forceps.

24th. The evening of the operation her temperature suddenly rose to 104.6° , falling to normal in four days. The rise in temperature was of course too sudden and too great to be the result of the operation. The cause of it was soon discovered to be a marked intestinal disorder which had begun the day before the operation. This fact was not communicated to me by her mother. No drainage was used and the wound was entirely well and the stitches out in five days. Her progress is very much the same as in case 1.

Case 3.—J. L. H., male, aged sixteen months. Was first seen by me on January 10, 1891. In the fifth month of her pregnancy his mother's friendly sympathies were deeply stirred by seeing the dead baby of a friend, and the seventh month of her pregnancy she was startled by being nearly run over. Her labor was normal, lasting three hours; no instruments were used. The child's weight was between seven and eight pounds. The anterior fontanelle was very small at birth and closed at or before seven months of age. The child was breast-fed for three weeks and after that bottle-fed. At about three weeks, six weeks, and three months of age had one or more convulsions. He was very peevish and fretful up to twelve months of age, but of late has been much less so until some recent trouble, presumably his teeth. His parents state that he was a "blue baby" for a year, but Dr. S. Striker, his physician, informs me that it was not discoloration due to a patent foramen ovale, but a constant and very marked mottling of the skin from defective circulation. The child has had attacks of very poor circulation, but of late these have diminished very much. He has also been subject to attacks of apparent pain and of restlessness continuing for a day or two.

Status Præsens January 10, 1891.—A well-nourished, apparently hearty boy; no contracture or other deformity excepting his head. Viewed in front the skull is markedly conical, face broad, top of skull narrow and arching. Circumference on the shaven scalp, 38 cm. (15 in.). Diameters: Occipito frontal, 13.5 cm. ($5\frac{3}{8}$ in.); biparietal, 9.8 cm. ($3\frac{7}{8}$ in.); bitemporal, 8.6 cm. ($3\frac{1}{8}$ in.). The child drools all the time, has never attempted to stand, falls unless held up, and scarcely even holds his head up. He has never talked. He moves his extremities, but very sluggishly; moans a little, sleeps poorly; head and eyes commonly turned to the left and upward, except in the attacks of apparent pain, when they go to the right, and, as his father expresses it, "he twists himself all up." These attacks are not epileptic in character. He yawns often. His attention can be attracted, but with difficulty, and only for a moment. On shaving the head, the broad furrow behind the coronal suture is very marked, and the occiput protrudes posteriorly much more than usual.

Operation, January 16.—Present, Drs. Striker, J. C. DaCosta and Mills. Dr. W. J. Taylor, as usual, assisted me. I thought that the child's circulation had at times been so impaired, that especial care was necessary in administering the anæsthetic, so I requested Dr. Coplin to give the ether, on account of his large experience in the Jefferson College Hospital. After the same method as in my former cases, I cut a groove $\frac{3}{4}$ of an inch to the left of the middle line, reaching from $\frac{3}{4}$ of an inch above the supra-orbital ridge well

back, nearly to theinion. Its length was $6\frac{3}{8}$ inches. In biting the bone I used a pair of forceps devised by me for the purpose, which answered admirably, so that instead of an hour and a quarter as in my first case, and fifty minutes in my second, I did the operation in thirty minutes. The bone bled quite freely, but not alarmingly, and the bleeding stopped spontaneously. No other incident occurred during the operation, except that the child's breathing at one time was sighing, and he had apparently, about the same time, a slight convulsion. There was tremor of the extremities during the operation. At no time was he deeply anæsthetized. Shortly after the close of the operation I left the child in its crib, in charge of a competent nurse and the mother. He was slightly pallid, but no more so than one would expect after an operation, and there was nothing in the respiration or pulse to cause anxiety. Dr. Taylor did not leave the house till an hour after the operation, when the child's pulse and respiration were entirely satisfactory. An hour and a quarter after the close of the operation, the child gave a few gasps and died instantly, presumably from heart failure. It had not recovered consciousness after the operation. No post-mortem examination could be obtained, in spite of the most earnest efforts.

Case 4 (Gerster and Sachs).—A. F., female, aged $4\frac{1}{2}$ years; labor normal, first child; began to walk after the age of 2 years; in third year began to speak a few words, but these she would use properly. When 13 months old had measles. At 15 months two distinct convulsive attacks, without paralysis. Other convulsive attacks at the age of 22 months and 29 months; none since. After these attacks grew more idiotic; lost what little speech she had, became unruly, fretful and ill-tempered; slept little. The fontanelles had disappeared. The measurements taken on shaved head were: Circumference, 31 cm.; fronto-occipital, from root of nose over top of head to occipital prominence, 30 cm.; biauricular, $32\frac{1}{4}$ cm. The child was operated under chloroform, the period of anæsthesia lasting not more than fifty minutes; linear craniotomy was done on the left side, from in front of the position of the coronal suture and beyond the lambdoidal suture. The opening in the skull was semicircular. The child's pulse was weak as soon as chloroform began to act; recovered nicely, however. Soon after operation was conscious, and pulse rallied. Without further accident child died suddenly, three and a half hours after operation, from acute anæmia.

Case 5.—In the *New York Med. Record*, February 21, 1891, Dr. John A. Wyeth reports a case of a male child, 11 months old, operated on by a median incision of the scalp from the nose to the occiput. Two lateral trenches, $\frac{1}{4}$ of an inch wide and $\frac{3}{4}$ of an inch apart, were made from just above the eyes to the occipital protuberance.

At each end a transverse cut was made in the bone on each side, and a similar transverse cut on each side at the middle. By the fingers these four bone flaps were then forcibly torn loose from the dura mater, widening the trenches from $\frac{1}{4}$ of an inch to 1 inch each. No injury seems to have been done to the dura. Time required, an hour and a half. Wound well without incident in ten days. A month later the improvement was "surprising and gratifying." The intelligence had greatly increased.

Cases 6 and 7.—Two cases reported by Lannelongue in *L'Union Médicale*, July 8, 1890, and of which a *résumé* appears in my clinical lecture in *The Medical News* of November 29, 1890.

Case 8 (Dr. J. C. McClintock's case).—A girl, aged 3 years and eight months, although appearing to be not over one year of age. Premature birth at eight months; no instruments. Anterior fontanelle closed very early. Totally blind; not the faintest signs of intelligence. Two years ago the orbital plate of the frontal bone on the right side gave way, displacing the right eyeball from the orbit. The knee joint became very painful a few months ago, and the arms and lower limbs contracted. Right tibia and fibula and left femur curved. Head narrow, forehead low. Linear craniotomy (March 28, 1891), on each side of the longitudinal sinus, with lateral grooves at the two ends. The tips of the fingers were then passed into the grooves, and the bones spread on each side until the quarter-inch grooves became an inch wide. The dura was not opened. Next morning the temperature was 103° , with rapid pulse, but soon subsided to normal. Entire union at the end of a week. The time is too brief as yet to judge of the result, but Dr. McClintock reports that the mother says that "since the operation the child is not so restless, does not cry nearly so much, and has required much less care and attention. The extremities are not so tender, and the child will try to play with any little article that is given to it." Before the operation she could only lie on one side; now she will lie on either side. The paralysis has almost disappeared, so that the left hand is used almost as readily as the right.

In considering these cases one is struck by the fact that two of them were followed by speedy fatal results. I presume it is only to be expected that children of such feeble cerebral development accompanied as in my own case (Case 3), with faulty circulation, should be less rugged and less able to stand the shock of an operation. The cause of death in my own case was very clearly, I think, heart-failure, and in Sach's and Gerster's case it was acute anæmia. This mortality, which is quite unusual of course in ordinary brain operations, should induce us to state the risk to the parents in stronger terms than we would were it an ordinary case of trephining.

For myself I cannot but think it a very fortunate thing, for if such children cannot be helped it seems to me that death is preferable rather than to linger in this world in such defective and helpless condition.

It should, however, make us especially careful as to the administration of the anæsthetic and we should use all possible means to shorten the operation as much as possible. The forceps I devised for the operation certainly answer the purpose very much better than those I first used, so that the time required for the last operation was only twenty minutes, instead of an hour and a quarter as in my first. In using them it is better to cut alternately a little to the right and left (as one turns his toes out in walking) to prevent their binding. It will be noticed that the upper blade is perforated. This perforation widens from the cutting edge upward, so that each piece of bone bitten out pushes its predecessor loose. In a recent case of spinal laminectomy I used the same forceps to remove the vertebral laminae, and I found them far superior to any of the other instruments I had on hand, and tried in turn.

I have not yet operated on both sides of the skull, and in view of our present experience I certainly would deprecate a simultaneous operation on both sides. Probably the additional shock would be very unwise and would add greatly to the mortality. Whether two lateral operations done successively will improve the condition of such children more than one remains to be seen. The results as to mental condition in the six cases that have survived may be stated briefly as follows: Lannelongue's second case was reported almost immediately, too early to judge of any results. So too of McClintock's case. In the other four children there can be no question of improvement, very rapid in Lannelongue's case, slower but sure in both of my own and in Wyeth's case. We have, therefore, I think, sufficient reason to encourage us to operate in other cases, and it is this fact, and the fatal result in two, which has led me to report my cases so early, before the final results are obtained. This will require several years, and meantime we ought to make known the immediate results as a guide in other cases.

In the *St. Louis Clinique of Physicians and Surgeons*, April and May, 1890, Dr. Louis Bauer reports the case of a young woman on whom he did a craniotomy for microcephalus. Her age, the measurements of the head and the date of the operation, are not given. Two buttons were removed from the right parietal bone, and the intervening bridge chiseled away. On May 9, presumably 1890, a second operation was performed, on the opposite side of the skull. Prior to the operation there was spastic paresis of the muscles with great tremor, which after the first operation had so diminished as to enable the patient to

thread a needle. There is no statement as to mental condition. She recovered from the second operation, but it is too early to judge definitely of results.

In *The Medical News* of January 3, 1891, Dr. Trimble, of Baltimore, reports the case of a child, 3 years of age, whom he trephined on November 8, 1890. On the right side of the middle line two buttons of bone, 1 inch in diameter and $\frac{1}{2}$ inch apart, were removed, so that the opening measured $2\frac{1}{2}$ by 1 inch. Some improvement was noted on December 6, 1890.

I have not included these cases under the head of linear craniotomy, since it seems to me that they should be considered simply cases of trephining for microcephalus and idiocy, as has previously been done by Fuller and others. The essential difference between trephining and linear craniotomy is this: that in linear craniotomy the intention is to make the entire side of the head a *bony flap*, as it were, whereas the trephining in the cases alluded to simply removed two buttons of bone and the intervening bridge, and so produced a difference in pressure and possibly allowed, simply at the point of trephining, a little bulging of the brain itself. As to the results, so far as the brief time in all the cases will allow us to judge, they seem to be quite as good after trephining as after linear craniotomy proper, and if so, it may be a matter of indifference which is done. But at the present time it seems to me more logical to do the craniotomy than the simple trephining.

The operation of Wyeth seems to me unwise, and likely to be followed by a fatal result in more cases than if the less heroic method usually employed is followed. Even this has resulted in two deaths already, and if a double operation is done and the two sides of the cranium are forcibly separated, the danger would seem to be far greater. The dura might easily be torn, especially as it is so adherent in children. Moreover, the brain cannot suddenly follow the widening bone, but must be persuaded, as it were, to occupy a larger room by favoring its gradual growth. This, I think, is better obtained by the process I have followed than by Wyeth's method. The same remarks apply to McClintock's case.

A SYSTEM TO DEFRAUD INSURANCE COMPANIES.—There is said to be a gang in Paris, the members of which thrive at the expense of the insurance companies. Their plans are simple. A man lets himself be run over. The driver is his accomplice. The authorities are appealed to. An insurance inspector reports on the case, making the slight injury sustained appear a very serious one. The profits are divided up. As occurrences like this became frequent, suspicion began to be aroused. The result ended in the imprisonment of sixty-five members of the gang.

DISLOCATIONS, UPWARDS AND BACKWARDS, OF THE SCAPULAR END OF THE CLAVICLE.

Read in the Section of Surgery and Anatomy, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 5, 1891.

BY WM. H. DOUGHTY, M.D.,
OF AUGUSTA, GA.

In the July No. of the *Richmond and Louisville Medical Journal* (now *Gaillard's Medical Journal*), for 1876, I published an article entitled:

"True Method of Treating Dislocations, upwards and backwards, of the Scapular end of the Clavicle, with report of a case illustrating the principle employed."

According to standard authorities such injuries are rare and their treatment extremely unsatisfactory. Since 1876 I have seen but two cases, both of which occurred within a few months of each other in 1888: one in my own practice, report of which accompanies this paper; the other in that of my friend and neighbor, Prof. Thos. R. Wright, of this city, through whose courtesy I am permitted to refer to it, and report an excellent result from the method of treatment given herein.

My first case was published in illustration of a new principle in the management of such injuries, and it was thought that the simplicity of the treatment and its satisfactory result would at least claim the attention of the surgeons, if not their approval of the principal then first enunciated. I am, however, not aware of its employment, or even recognition by others, a fact that induces me to present it before this body on this occasion, with two additional cases, perfect in their results, to support its claims to confidence and adoption. Hamilton, in sixth American edition of his great work on "Fractures and Dislocations," Wyeth, Ashurst (*Encyclopædia of Surgery*), still detail the old imperfect methods.

The wood-cut given with the first case was intended to show the position of the arm, mode of dressing for maintaining this, and the permanent reduction and retention of the displaced end of the bone. It was a poor "cut," a libel on an excellent photograph from which it was made, taken soon after the dressings were applied. The photograph accompanying the present report shows the *result*, having been taken six weeks after the injury; the loose worn bandage bespeaks its own superfluity, having been used longer than was actually necessary to prevent the premature use of the arm by a thoughtless youth. As to the permanency of this result, I may report that an examination of the parts in March, 1891, nearly three years after treatment, revealed an altogether satisfactory condition. I wish also to state that a similar examination of my first case after the lapse of twelve years

showed a reproduction of the displacement, although at the time of discharge of the case it was fully restored as then reported. This fact suggests the necessity of restraining the early, free use of the limb with laboring men as an additional protection against the return of the luxation. The acromio-clavicular articulation is perhaps one of the weakest in the body, surgically speaking, and may need therefore greater attention in this particular, especially with adults, subjects of injury.

Of the three cases now reported under this method of treatment two give unquestioned

backwards against the side of the chest, thus stretching to the utmost the fibres of the deltoid arising from the outer third of the clavicle, and antagonizing the trapezius whose vigorous action maintains the displacement; and further, rotating and fixing the scapula by drawing upon its attachments (muscular and otherwise), to the humerus. The arm is then secured firmly and immovably by wide strips of adhesive plaster encircling the body and arm.

Injured June 1st, 1888. Photographed July 13th, 1888 (6 weeks), when bandage was removed. Illustrates result.

satisfactory and permanent results, while under former methods the latter were so rare that Hamilton says: "my notes furnish only *two* cases of perfect retention after a complete dislocation at this point" (p. 566), having recorded forty-one cases in all.

For the benefit of those who may not have read the former article on this subject (copy of which is enclosed herewith), the principle referred to, briefly stated, is as follows: *In lieu of direct pressure on the displaced end of the clavicle, made by pads, straps, bandages and other similar devices for retaining the same in position, it is suggested to draw the arm forcibly downwards and*

Illustrates position of arm, mode of dressing for maintaining permanent induction, etc.

It is not necessary to encircle the arm first (see photograph of first case) and then the body and arm together, as there is liability when this is done to great tumefaction of the forearm and hand, as my second case developed.

A little reflection will satisfy the thoughtful that there is gained by this mode of management, as nearly as possible, the immobility of the scapula, the requisite antagonism of the trapezius by the deltoid, with the consequent replacement and retention of the displaced bone.

All of the structures about the shoulder-joint, thus drawn upon, aided by the substantial leverage of the humerus when pressed upon the side of the body, sustain the deltoid and contribute to the result. Moreover, the rotation of the scapula rather relaxes the fibres of the trapezius inserted into the spine of the scapula, while those of the deltoid arising therefrom are pulled upon. The position of the end of the clavicle, no longer free to move, is the mathematical resultant of the operation of these opposing forces, now equally balanced.

Thus, quoting from my former article, "by this simple mechanism was beautifully illustrated that cardinal principle in the surgery of dislocations, namely, that their safe and proper reduction and treatment can best be secured by a careful study of the muscular action that maintains the displacement (a factor in its production also), and the relations of the muscles that normally antagonize it." (P. 4).

By this plan of permanent adjustment the shoulder is left open to inspection at all times, and the bungling, irksome apparatus of every kind, heretofore employed, is dispensed with.

Report of Case.—On June 1, 1888, Herbert C., about 14 years old, was thrown from a road-cart, violently striking the right shoulder; was immediately disabled thereby, and complained of great pain in the shoulder and inability to move the arm.

An examination showed, besides a contusion of the soft parts about the shoulder, a dislocation upwards and backwards of the scapular end of the clavicle. The extent of the luxation was sufficient to produce a bulging of the fibres of the trapezius, very distinct, when viewed from all directions. Dislocation was easily reduced and bone maintained in position by method detailed elsewhere. Result was entirely satisfactory as will be shown by accompanying photograph taken on July 13, six weeks afterward.

SUGGESTIONS ABOUT ABDOMINAL AND PELVIC SURGERY.

Read in the Section of Obstetrics and Diseases of Women at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY WM. H. WATHEN, M.D.,

OF LOUISVILLE,

PROFESSOR OF ABDOMINAL SURGERY AND GYNECOLOGY, KENTUCKY SCHOOL OF MEDICINE, ETC.

The recent contributions upon abdominal and pelvic surgery are probably more numerous and practical than upon any other department of general or special surgery; still, there is a variety of opinion as to the best methods of treating pathological conditions within the peritoneum, or as to the immediate or permanent results of the many procedures that have been practiced.

This is especially true of pelvic surgery, where we find, in the practice of the most experienced and successful operators, accidents during the operation and complications following it, for the prevention of which, there is no united opinion as to the correct technique to adopt; nor is it always possible to explain why troublesome complications occur in one case, and do not occur in another apparently similar case. Careful observation and experience may finally teach us much wisdom in these matters, and I will ask your kind indulgence while I briefly allude to a few things that may be of value, if carefully discussed by the members.

There is too much laparotomy done and too many men are doing it; men who know too little about the diagnosis and pathology of abdominal or pelvic diseases, or about the best technique in operating, and have few facilities for doing such work. Continuously good laparotomy work cannot be done except by men who largely devote themselves to this department of special surgery, and with such men some cases are operated on where the indications do not justify it. The appendages are sometimes removed for vague nervous troubles, where there is no disease of the ovaries or tubes, or peritoneal adhesions. Such cases are made worse, and are mutilated in a way that cannot be corrected.

The pendulum has swung too far, but many of our best operators are earnestly urging upon the medical profession that the operation is not indicated except in cases where there is well defined disease that has resisted, or will resist, other more conservative means.

As the experience of an honest surgeon widens, he operates relatively less frequently, and he can recall cases that he does not believe should have been operated on. An honest, intelligent and careful man may, when young in observation and practice, make mistakes in the selection of suitable cases for laparotomy, but this is less frequent than it was a few years ago. It is criminal to do dangerous or capital operations while ignorant of the best methods of doing such work, or for the purpose of adding a little cheap glory to our reputation; or to report cases that apparently recover from the immediate effects of the operation as permanently relieved before the final results can be appreciated. Such men usually have many bad results or deaths that they do not report so promptly, and the profession, or the people, seldom hear much about them.

I have reported but a small minority of my successful cases, but have promptly reported my bad results or deaths, because by a careful study of such cases, we finally do better work, by learning how to avoid or prevent complications or accidents that may cause the death of our patient. Reported recoveries in simple cases of laparotomy do not always indicate superior or unusual skill in

the operator; and such reports are of little value to the medical profession, and may indirectly result in the death of many women, by influencing ignorant men, with no facilities for such work, to attempt it because of its apparent simplicity.

What I may say relative to the technique, etc., of laparotomy, refers to cases where the conditions are manifestly such as to positively indicate the necessity for the operation. In preparing for an operation, the physical and mental condition, and the hygienic and sanitary surroundings of the patient, should be made as perfect as possible under existing circumstances; and unless absolute surgical cleanliness is observed in everything that may come in contact with the wound or peritoneum, septic infection may follow.

Some operators, who talk a good deal about antiseptics, do not know how to be surgically clean, because they have not learned to appreciate the value of cleanliness in every detail before and during the operation. The infection often comes to the patient by the neglect of little things, without the strict observance of which no one can be a successful abdominal surgeon. The danger from atmospheric infection is practically *nil*, as has been shown by experiments, and by the continuously good results of operations done in large amphitheatres before several hundred students. It may be possible for septic matter to reach the peritoneum through the intestinal walls, but this has not been proven. A spray of antiseptic solutions is not necessary, and if strong enough to kill pathogenic germs supposed to be floating in the atmosphere, it is positively poisonous.

Some men who use the spray Don Quixote-like, while pursuing an imaginary foe allow the deadly enemy to enter through numerous neglected channels—the hands, sponges, sutures, instruments, etc. Every operator should of course observe the broad principles that make the foundation of all good surgery, but if he neglects the details, he will be disappointed in the results. Asepsis is more easily accomplished in well regulated private or public hospitals or infirmaries; in private houses septic matter may more readily be introduced unless the operator, or an experienced nurse, rigorously superintends everything before and during the operation.

That we may better appreciate the practical significance of my position as to what constitutes asepsis in laparotomy, I will give some of the methods before and during an operation. I prefer not to operate in a room where the patient is afterward to stay, and when I am compelled to do so, if delay is admissible, I have the room thoroughly cleansed and ventilated for twenty-four hours before the operation, but use no spray or other means of disinfection. When it can be done, I operate in a specially prepared laparotomy room at St. Joseph's Infirmary, so

arranged that everything in or about the apartment can be kept aseptic with but little care. The operating tables for the surgeon and nurses have plate glass covers, and the trays for instruments and pans for sponges and dressings are white porcelain lined.

Everything is carefully cleansed before each operation, and the operator and his chief assistant take a bath and put on clean linen, and white aprons reaching from the neck to below the knees and extending entirely around the body, so as to prevent the hands coming in contact with anything unclean. The towels are carefully washed and boiled, and are used for no other purposes. Soft and well-shaped sponges, free of sand or grit, are selected, and after being carefully washed, are made aseptic after the method of Greig Smith: Eight ounces of bisulphide of soda and four ounces of oxalic acid are dissolved in a gallon of water, in which twelve to twenty sponges are immediately immersed and kept for ten minutes; they are then washed by frequent changes of water for one hour, so as to get out all the sulphurous acid and sulphur. This is quite a labor, but it insures perfect freedom of septic matter. They are then wrung out of the water and put into a clean cotton or linen bag so as to keep out the dust while drying. When dry, they are put in large ground-glass-stoppered bottles or jars, and may be kept indefinitely in a pure condition.

Sponges once used may again be made aseptic by the same process, but I prefer not using them a second time if they have been soiled in septic matter. If a sponge comes in contact with anything that may be unclean, it is not used until again prepared. Chinese hard-twist silk of three sizes is used. It is purchased in unbroken packages, and wound loosely on separate glass spools. These are put into glass test tubes, which are stoppered with a piece of absorbent cotton and then sterilized. They are kept in the sterilizer for an hour, for three consecutive days. The silk is now so free of bacteria that a culture could not be made from it, and if the cotton is not removed it will stay in this condition. Each tube contains enough silk for a laparotomy. The silk and needles are kept during the operation in sterilized water at a temperature of 212°. This may not be necessary, but if the cotton has been partially displaced from the tube, it would be a wise precaution.

In the same boiling water I keep the small glass drainage and the large irrigation tubes. As our hydrant water is generally muddy, I use sterilized water, and always have it boiled before operating in vessels kept for this special purpose. The instruments are washed with sapolio or some strong soap, and boiling water is poured over them. When I begin the operation, the hairs of the brush are pushed through the eyes of the

needles and the holes in the instruments so as to get away all poisonous matter. It is well to have instruments, towels, dressings, etc., sterilized for an hour before using them, but they should be thoroughly washed before sterilization.

The patient is given one or more hot baths by a well trained nurse, the vagina and rectum are washed with copious injections of hot water, and the pubes is shaved. Before making the abdominal incision, the abdomen is again washed with soap and brush, and wiped off with sulphuric ether. Dry towels covered by towels wrung out of boiling water are placed over the abdomen to prevent anything possibly unclean coming in contact with the hands or any of the appliances used.

The nurses in charge of the sponges, needles and sutures are as aseptic as the operator. I use no antiseptic solutions, but use for sponges, instruments and hands boiled sterilized water kept as hot as can be borne. If everything is aseptic we don't need antiseptics, and they may cause general or local trouble. I will refer to but a few points in the technique of the operation. Adhesions are carefully separated close to the tumor or structure to be removed, or the uterus, to prevent hæmorrhage or wounding the intestines or bladder. Adherent intestines should be separated if possible; otherwise the operation is incomplete, and the patient will not probably be permanently, if at all, relieved.

The patients sometimes suffer more after the operation than before it, because of the extensive adhesions induced by uncleanness, antiseptics or traumatism committed by a careless operator. I believe adhesions will be fewer if antiseptics are absolutely excluded from the operating room, and are not even used for the instruments or the hands. This may seem heterodoxical to many, but I have arrived at this conclusion, after experience and careful observation. If the instruments and the hands are clean, we need no antiseptics, and if they are unclean, the solution will not cleanse them or prevent infection, but may so irritate the peritoneum as to cause few or many adhesions. It will require more experience to decide how much damage is done in this way. Blood, pus and all foreign matter should be removed, and great care should be practiced to prevent rupturing a pus sack or cavity in an operation for their removal.

When any foreign matter except blood has gotten into the cavity, it should be thoroughly irrigated by hot sterilized water. This is not only the best way to cleanse the peritoneum, but it is also an excellent means of preventing or treating shock. This may be done by attaching one end of a three-foot piece of gum hose to a glass tube, and the other end to an iron granite funnel, into which water is copiously poured and forced by hydraulic pressure through all parts of the abdomen and pelvis.

The drainage tube is invaluable in many cases, but if improperly used it is capable of doing much mischief. There are many cases in which it is indicated; there are many in which it is not. It should be used if we close the abdomen before hæmorrhage has ceased, or if foreign matter, that is possibly septic, has got into the abdomen. It should be attentively cared for and frequently emptied with a long nozzle syringe by a well-trained nurse. It should be very small and light, with open end, and numerous fine openings on the sides. It should be carefully placed, and long enough to enter to the deepest part of the pelvis.

After the dressings are applied around the tube, a twelve-inch square piece of gum dam, with a small hole cut in the center, should be closely fitted around the neck, so as to keep the dressings clean. If a piece of absorbent cotton is kept over the mouth of the tube, and held in position by folding over the gum cloth, it will absorb discharges and remove the danger of sepsis from the introduction of pathogenic germs. It should be removed when soiled and a new piece used.

Some of our best known laparotomists use two long drainage tubes, and do not protect the dressings and the wound by the gum dam. A small tube will usually drain as well as a large one, and it does not subject the patient to so many dangers.

While it has been shown by Grawitz that the peritoneum may render harmless, and dispose of cystic fluids, pus, or pathogenic germs, it would be reckless to expect it to do so when we may supplement the efforts of nature by the use of a drainage tube, through which irrigation may be used if needed. The long nozzle syringe, or a syringe with a small gum tubing attached, affords the best means of emptying the tube, and this can be done aseptically. The practice of trying to drain the peritoneal cavity by introducing strips of gauze or wick into the tube to its bottom, or allowing shreds to enter the cavity, as practiced by German laparotomists, is bad surgery, but may be a means of introducing septic matter. While aseptic gauze may usually drain efficiently, it sometimes prevents drainage and causes the blood to coagulate in the tube. This is especially true where capillary drainage is attempted by the use of the wick. I have never seen the slightest tendency to coagulation where the syringe was used. Probably the most correct exposition of the methods of drainage in Germany will be found in the paper "Drainage in Laparotomy," by Sängner, of Leipzig, at the recent meeting of the Tenth International Medical Congress at Berlin. No mention is made of protecting the dressings from the discharges by the use of gum dam, or of removing the secretions by suction with the syringe.

Vaginal drainage, with possibly a few exceptions, should never be attempted, though Dr. August Martin, of Berlin, and other German operators, frequently practice it. It can accomplish nothing more than supra-pubic drainage, and subjects the patient to greater dangers from sepsis. The tube should be removed as soon as the conditions will admit, and when bleeding has practically ceased, and there is only a small quantity of clear inodorous liquid removed, it is no longer needed. If the tube has to be retained more than forty-eight hours, it should be rotated a little twice daily, so as to facilitate drainage by preventing obstruction in the small openings.

The dressings need not be disturbed to remove the tube, and in a few weeks the place where it was introduced can scarcely be detected; and ventral hernia will not occur at this point more easily than at any other part of the incision. Hernia will seldom occur if we are careful to unite the ends of the abdominal fascia. This may be done by the deep suture if the fascia is drawn out and the needle correctly introduced, but the separate suturing of the fascia is more reliable.

Recognizing the fact that in laparotomy work death is too often caused by septic infection, and that this can nearly always be prevented, I am deeply in earnest in my desire to aid in impressing upon the medical profession what I conceive to be the best means of preventing the introduction of septic matter. As death occasionally follows prolonged anæsthesia in organic disease of the heart, lungs or kidneys, we should carefully examine these organs before we decide to operate.

with tapes or rods, must in no way be connected with the handles, which must move freely in all directions, and still another is that rotation and flexion of the head can only take place when Tarnier's instrument or others similar to it are used. Tarnier's instrument, when clamped to the infant's head, interferes with rotation. These ideas I believe are detrimental to proper axis traction, as it is well known that, in the skilful use of the forceps, we should frequently unlock the blades that the head may undergo rotation and accommodate itself to the pelvic canal.

Pajot, Hubert, Morales and Albert H. Smith, all recognize that axis traction can be made without any such complicated attachments to the ordinary forceps.

With the following instrument, which was described in the *American Journal of Obstetrics* for December, 1889, we can make ideal axis traction during the entire passage of the fetal head with remarkable ease and safety. In cases where much strength must be employed, you cannot perform axis traction properly with the common forceps by Pajot's, Smith's, or any other manœuvre.

FIGURE 3.—Method of holding the forceps.

AXIS TRACTION AND A COMBINED AXIS TRACTION FORCEPS; ALSO AN ANTI-CRANIOTOMY FORCEPS, TO BE USED AS A SUBSTITUTE FOR CRANIOTOMY AND VERSION IN PELVIC DEFORMITIES.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 1891.

BY T. J. MCGILLICUDDY, M.D.,

INSTRUCTOR IN OBSTETRICS AT THE NEW YORK POLYCLINIC; OBSTETRICIAN TO THE NEW YORK MOTHER'S HOME MATERNITY HOSPITAL; SURGEON IN CHARGE OF THE YORKVILLE DISPENSARY AND HOSPITAL FOR WOMEN AND CHILDREN, ETC.

The correctness of the principle of axis traction is now, of course, conceded by all, but there are still many fallacious ideas in connection with its production. One of the most common is, that it is necessary to have rods attached to the blade by a movable joint, and this idea has been followed by about all the imitators of Tarnier's models. Another is that the traction, whether

The advantages claimed for this instrument are:

1. That with its use axis traction is simple and uncomplicated.

2. That it is superior to Tarnier's in the fact that while using it, axis traction at the superior strait is perfect.

3. That while, in relation to Tarnier's instru-

ment, a great deal has been said of the indicator, in this forceps the indicator is in the hands of the operator, and tells his *conscience musculaire* the direction of traction, as well as the resistance.

4. That it does away with the trouble of Pajot's, Smith's, or other methods, and in its use one has plenty of power and perfect control.

5. That it is easier to make rotation in the posterior positions with the adjunct handles, if it is thought best to use the forceps for that purpose.

6. That it is easy of application, and in its dual character, it has all the advantages of axis traction and the ordinary forceps, and saves the expense of buying two instruments where one will do.

The Tarnier instrument is complicated, cumbersome and expensive, thus nullifying its good points, and has been condemned by the Paris Obstetrical and Gynecological Society for these reasons.

W. Robb to see with him a little girl of 3 years, who had several hours before fallen three stories in a hallway and, striking the tiled floor, fractured her skull. The line of fracture running from the mastoid region over the vertex to the other side, and the occipital portion was driven by the blow under the other part over half an inch, compressing the cranial contents to at least that extent. After prying the occiput back into position, the parts were treated antiseptically, and the patient made a rapid and complete recovery. The whole upper segment of the infantile brain, including the biparietal and bitemporal portions, is relatively its non-vital part, and will stand very considerable compression without danger, while the bimastoid or basal region is the vital portion, which Nature has so wisely protected by making it incompressible. I think it is conceded that the death of the infant is generally caused, where the ordinary cephalotribe is

FIGURE 4.—Axis traction. (Modified from Charpentier.)

The forceps has an undoubted place as a compressor in certain cases. We are at all times to follow Nature's guidance. Who has not seen a foetal cranium elongated an inch more or less, and generally distorted, by the moulding to which it has been subjected in its passage through the pelvis, and yet no damage has been done to the cranial contents. The following case will exemplify the amount of compression the brain will sometimes stand even in children:

About two years ago, I was asked by Dr. S.

used, by the close approximation of the tips, thus fracturing this part and causing pressure on the medulla. Many cases are recorded of depressions, indentations, and even fractures of the arch of the infantile cranium, with rapid and complete recovery. Therefore, as some compression of the infant's head is compatible with its safety, and as there is no modern instrument that I am aware of, that stands between the ordinary forceps and

the cephalotribe or cranioclast, there can be no doubt of the utility of this, which is intended as a substitute for delivery by craniotomy or version in cases of pelvic contraction of minor degree, or where the common forceps is unsuccessful. It is an effectual tractor, and as the blades are sufficiently strong to prevent feathering, there will be no slipping. It makes moderate transient compression of the flexible infantile cranium in its upper portion, while it does not press too strongly on the child's neck with its tips. Thus it gives the child a chance for its life while it minimizes the risk to the mother. It is safer for the mother than craniotomy, because it terminates the labor more speedily, and there are also no cutting instruments to slip, and no spiculæ of bone projecting to tear the maternal parts. It is also quicker and better than turning, as transient compression of the flexible foetal skull by the forceps is no more dangerous than compression by the contracted pelvis in version, and traction by the forceps is much less dangerous than traction by the lower extremities, which frequently disjoints the neck, compresses the funis and even decapitates. We must not alone look to the safety of the mother, but we must also have some regard for the safety of the infant. Turning may be better, in skilful hands, than leaving all these cases to nature, and it is an excellent substitute for craniotomy, because if you cannot get the head out, the compression on the cord kills the child, and perforation is then justifiable. With this forceps I believe we have something superior to either.

FIG. 5.—Illustrating the effect of lateral compression upon the sides of the cranium after the use of the forceps, after moulding and after turning. Showing also its double conical form, or rather its olive-shaped form.

The argument of Simpson that after turning, the bimastoid diameter is an apex to the cone-shaped head, and the biparietal diameter the base, and delivery is consequently easier, may be true when the forceps are not used; but the application of the forceps changes all this, and makes the bimastoid diameter the base of the cone, when it compresses the biparietal portion (Fig. 5). He believes "that the necessary degree of compressions would be effected more easily and by a less amount of force if the head

were drawn through the narrow pelvis as a footling presentation than if it were driven into it as a cephalic presentation." I am sure that with the use of this compressing and traction forceps, and from the character of the cranial bones, that not only will no more force be required, but there will be greater safety for the infant. The question is, whether the uterine force, acting on the breech, plus the traction on the forceps, is greater than the uterine force acting on the head, plus the traction on the body, and with which we are justified in using the greater force.

Simpson's Conclusions in Favor of Turning are :

1. The foetal head has the shape of a cone with the base upward, and when the trunk is delivered, the smaller part of this cone may usually engage in the superior strait.
2. The solid hold given by the body of the foetus when it is delivered first allows us to use force enough to cause compression of the head, and to bring, if need be, the elastic and larger part of the cone into the greatest space in the contracted pelvis.
3. The head, drawn through the contracted pelvis, generally so adapts itself, or may be caused to adapt itself, in such a manner as to bring its smallest diameter, the bitemporal, instead of the biparietal, into the most contracted diameter of the pelvic strait.
4. The cranial vault is more readily compressed when the force is applied to the lateral surfaces, as it is in the case of the after-coming head, and not as in the case of the before-coming head, partly to its lateral and partly to its superior surfaces.

In justifying these theories he arrives at the following conclusions :

1. The duration and hence the danger of labor is diminished by version. Therefore version should be resorted to as soon as dilatation is complete, without waiting for engagement of the head and in consequence before inertia can set in.
2. Compression of the foetal head is compatible with its life.
3. The traction to which the foetal neck is subjected is not incompatible with foetal life.
4. The risk of death from compression of the cord is not great enough to cause rejection of version.
5. Energetic but rapid compression is less dangerous to mother and to infant than less but prolonged compression.
6. Local lesions of vagina, fistule, etc., are more likely to result from forceps than from version.
7. The risk of rupture of the uterus during version has been exaggerated.

Conclusions in Favor of the Anti-Craniotomy Forceps.

1. The foetal head, after moulding or application of the forceps, has the shape of two cones placed base to base, and, like an olive, either end may engage in the superior strait.
2. The anti-craniotomy forceps gives a much better hold, and causes slight compression if needed.
3. The same thing occurs in cephalic presentation.
4. With moulding and application of the forceps you compress not only the lateral surfaces, but the fronto-occipital surfaces as well.

In favor of anticraniotomy forceps.

1. It is not diminished as much as when this forceps is used and it can be used, if necessary, before engagement of the head as well as after.
2. If that is true why not use the forceps?
3. The traction to which the foetal neck is subjected often kills the foetus and sometimes decapitates it.
4. There is no risk of death from compression of the cord in the use of the forceps.
5. It is the same with the forceps.
6. Local lesions generally result from impaction with delay, version, and least of all from improper use of the forceps.
7. Much more risk of rupture with version than with forceps.

No woman should be delivered except by axis traction, and with these axis traction handles you can determine the exact amount of resistance, and the proper amount of force to use, and readily and easily use it.

Dr. Leischman, in writing of the long forceps

and high operation, says: "It is now very generally believed by those who have had the greatest experience that a large proportion of the unfortunate results depend upon improper instruments, and especially upon the use of such as are deficient in power. The observations which, on this point, we have already quoted from Dr. Barnes, apply here with peculiar force. Power and control are correlative factors toward the attainment of the result which we desire, and if there is a deficiency in the former, we can have but little confidence in the issue of the case." With this forceps we pull directly in the axis of the brain. One cannot grasp the handles of the ordinary forceps with comfort with both hands and still make any great axis traction. Most physicians say that the hands become cramped and lose all their muscular power after pulling a short time.

FIG. 6.—Illustrating the vital and non-vital portions of the fetal cranium, and thus showing where pressure may be made.

This instrument is not a cephalotribe or cranioclast, but a conservative, life-saving forceps, to be used in cases of considerable pelvic deformity. The following are some of its dimensions:

Length, 16 in.; length from lock to tips of blades, 9 in.; length of handles, 7 in.; length of axistraction handles, 4 in.; average width of blades, $1\frac{1}{2}$ in.; greatest width between blades when closed, $2\frac{1}{2}$ in.; width of tips of blades when closed, $\frac{3}{8}$ in.

When the head is high in the pelvis the operator should make a careful estimate of the conditions present, the obstacles to be overcome, the size of the child's head, etc., even if he has to insert his hand into the uterus. We must apply the forceps to the sides of the child's head when it is possible, but we must also do it when there is room. If the instrument is properly used it will do no harm. It is shown by Winter (American System of Obstetrics) that the forceps, in contracted pelvis, has caused less than fifteen per cent. mortality.

Midwifery as an art, and the technique of Cæsarian section as an operation, has improved to such a degree that craniotomy on the living fœtus need never be performed.

Osiander the elder, in forty years of practice, never did craniotomy. Dr. Alonzo Garcelon, in whose office I had the honor of being a student, in an active practice of over fifty years, never did the operation, and Dr. More Madden, in over

26,000 cases, never performed it, and never saw a case where it was indicated. The conclusion to which I have arrived is, that when this instrument cannot deliver a living child, there is no other operative alternative but Cæsarian section, as the revolting operation of craniotomy on the living fœtus is not justifiable. It has not been an uncommon thing some years since in England for a single practitioner to report forty or fifty cases of craniotomy. The child is exactly the same in utero as it is after birth; the only change is in the surroundings; and to kill it before birth is as much a crime as to kill it after.

The instruments described are made, among others, by Mr. E. Ackerman, 153 W. 29th street, and sold at \$6 and \$8 respectively.

THREE CASES OF EPITHELIAL GRAFTING FROM THE HORNY EPIDERMIS, WITH REMARKS.

Read in the Section on Surgery and Anatomy at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY C. B. KIBLER, M.D.,
OF CORRY, PA.

Practical example is always in advance of theoretical precept, and so in this paper we will present in practical work, to demonstrate the operation, technique, material used, and clinical results in a few cases of what doubtless is a new and novel procedure in epithelial grafting. Appreciating the fact that the researches of Reverdin, first announced in 1870, of the transplanting of small particles of skin to a raw or granulating surface, and the wonderful excellent results obtained by many operators by this method since then, as well as the most admirable results obtained through the method of Thiersch and others by removing long strips of skin from the thigh or arm and applying to much the same condition of surface as that of Reverdin, has to a greater or less degree superseded the method of the former and made the raw ulcerating surface of the past a thing not to be dreaded by the surgeon of the present day, as it many times was the surgical approbrium of the last decade. There is no question of doubt but to America belongs the credit of first advancing the idea and technique of skin grafting. The late lamented F. H. Hamilton, that master mind, who was always in the advance guard of improvement in American surgery, in 1854 successfully transplanted skin to a raw surface. He had, however, seven years previous, in 1847, advanced the idea but failed to apply it to use until later on. We will not burden the Section with reviewing the history and the great achievements attained in the past upon this subject, but will detail briefly the object of this paper.

Case 1.—In October, 1889, J. L., a lad of 12 years, in attempting to jump from a moving freight train, had the soft and bony part of his right hand crushed under the wheels. Efforts were made to save the hand, but some five or six days afterwards I was called in to amputate it on account of sloughing. The thumb retaining some life, the hand was disarticulated at carpo metacarpal joint, leaving a stump of 24 square inches entirely devoid of skin. His mother earned her daily bread as a washerwoman. Her hands, from her daily avocation, became much callosened, and it was from this thick and indurated epithelial tissue that I obtained what proved to be most excellent material for grafting. Small pieces, about one line square, very thin, in fact not much thicker than tissue paper, were sliced with a sharp scalpel from the callosities of the palmar surface of his mother's hands. The granulations were first washed with 10 per cent. solution of warm creolin water and afterwards with saline solution of sterilized water. The surface from which the grafts were to be obtained was treated in similar manner; the grafts of epithelium, about six to ten in number, were then applied to the raw surface and covered with protective, which was held in place by rubber plaster; the remainder of the wound was dusted with powdered boracic acid, and the whole covered with moist gauze over which absorbent cotton, and lastly crinoline bandage. The dressing was changed every three or four days; all dressing removed, and new grafts applied upon a new field of raw surface. About 80 per cent. of grafts adhered and formed true skin covering. One peculiarity it will be well to call your attention to, and that is, the grafts must be applied precisely as they are cut off, for if you should reverse or turn them over, they will not grow, seemingly the vitality is entirely destroyed. This hand was covered with skin in about four weeks' time.

Case 2.—My next opportunity for applying this mode of grafting, occurred shortly after the above case. Mr. K., age 63, had a tank of boiling water emptied upon his neck, back, arm, and forearm, entirely destroying 400 square inches of true skin. This was covered after the method as above related, it requiring nearly five months to complete the cure, with very little contraction from cicatricial tissue.

Case 3.—Large indolent ulcer of left leg. Mrs. T., age 56; the ulcer was about three by six inches in size, of three years' standing, the surface of which was prepared for the grafts by denuding the surface of same with scalpel before applying the grafts; five weeks was required to complete a perfect cure, and has remained so since December last.

The advantages in this method over the use of skin, either in large or small patches, consists in the fact that there is no pain, or raw surface left

upon those who furnish the material, that the supply from the hands of those whose avocation produce the callosities is daily renewed and no discomfort in any way is produced by removing the thin slices of tissue from the thickened epithelial surface, that from three to six or more grafts can be cut from the same surface every three or four days without the subject suffering the least inconvenience; at the same time it is entirely bloodless. No local anæsthetic is required, a much greater number, or percentage, of the grafts uniting than in any other method, for in my hands and others it has exceeded 80 per cent. of grafts that united and formed true skin. The abundant supply of material to be obtained at all times, without any coercion, for if it cannot be obtained from the palmar surface of the hand no trouble will be experienced in procuring it from the planter surface of the foot, where callous epithelial tissue can be obtained from the foot of almost any person.

If I have interested you with this brief summary of my experience in this new form of epithelial grafting, and in your hands after faithful trial if it proves as complete a success as in mine, I shall feel warranted in saying that in a great majority of cases, where now other methods are used, this can be substituted.

THE NATIONAL TEMPERANCE HOSPITAL.

Read before the National Medical Temperance Convention, Staten Island, N. Y., July 16, 1891.

BY J. DAVIS, M.D.,
OF CHICAGO, ILL.

Taking a panoramic view of human life as far back as history or legend extend, we find that progress of mankind has been marked by a continuous evolution of mind. The objective point of man's ambition has ever tended toward the happiness of the race. As this evolution of thought has progressed, man has comprehended his environments and learned how to bring himself into harmony with his surroundings. He has learned the value of the constituents of the air he breathes, and discovered that oxygen is necessary in unlimited quantities for life and health. Civilization has taught him that his habitation should not only be beautiful, but well ventilated. He has found that for perfect physical health, his raiment should not alone be for ornament, but that in clothing his body, certain well defined physical laws cannot with impunity be violated. The same truths have been demonstrated when he has sought to determine what to eat and drink to sustain life. Through knowledge gained by experience and observation, he has improved the diet of his barbarous ancestry. He has endeavored to eliminate that which was found

to be injurious, and to retain the most nutritious. By so doing, he has added to the strength and beauty of the human form. And still the evolution of thought goes on; still we are making new discoveries, and finding that for thousands of years we have been traveling the pathways of error. The work is not yet completed. Man is not yet a perfect being—reason does not always guide—passion, appetite and desire still control individuals and, in many instances, nations.

Some time in the remote past, it was discovered that by the decomposition of fruit and vegetable juices containing sugar, a liquid was obtained, which, when drunk, produced a peculiar condition of exhilaration. This anæsthetic effect which they had over the nerve centres made these liquids much sought after. The knowledge of the methods of their manufacture spread rapidly over the entire civilized world, and the most extravagant claims were made as to their efficacy in health and disease. The secret of the popularity of these liquids has been, and is yet, the soothing effect resulting from the alcohol they contain. The destructive effects of these alcoholic preparations on the human system have been observed by thinking men for hundreds of years, and during this period, many spasmodic attempts have been made to stay the consumption of a poison that has seemed to threaten the destruction of mankind. But appetite has always baffled and smothered the voice of reason.

The one *great* hindrance that has stood in the pathway of reform has been the multitude of pathological conditions for which alcohol has been recommended by the medical profession. The average man is always glad of an excuse to gratify the craving of his appetite.

But mind ultimately triumphs. The evolution of thought has been at work upon *this* subject. In looking back over the history of the temperance movement for one or two hundred years, it is interesting to note the gradual steps of thought through which the mind has risen, 'till the subject occupies its present scientific aspect. At one time it was supposed that none of the alcoholic liquids were injurious, so long as they were not imbibed to the extent of intoxication. Again, it was suggested that the evil came only through the distilled preparations, while the fermented and malt liquors were harmless. Some of the temperance societies strongly advised that the use of ardent spirits be permitted on social occasions. It is only within the last few years, that organizations have come into existence on a platform of total abstinence.

Along with these views, the medical idea of the subject has been gradually gaining attention. The therapeutical application of alcohol has been growing more and more restricted. Slowly but surely, the evolution of thought has been unfolding the truth. It will not be necessary for me,

in the brief space of this paper, to go over step by step the various experiments which have led up to the present scientific estimate of the case. It is sufficient to state, that it is now pretty satisfactorily demonstrated that alcohol, when taken into the system, is not assimilated, but acts as a foreign irritating substance, and is ultimately thrown off from the system, unchanged. It may also be stated that, while passing through the body, alcohol so acts on the various organs and tissues as to disturb the physiological processes, and in this manner, gives rise to many of the diseases which afflict humanity. If these declarations be true, then alcohol is neither a food nor a medicine.

Recognizing these great truths, and observing the destruction of human health and life going on all over the world from the use of alcoholic liquors, some of the most intelligent members of the Woman's Christian Temperance Union met a few years ago, and organized the National Temperance Hospital, as an institution in which to demonstrate to the world, that disease could be *more* successfully treated without than with the use of alcohol. In the organization of such an institution, many conflicting ideas had to be taken into consideration. By some it was suggested that alcohol be completely abandoned, both in the preparation and administration of remedies. Again, it was thought that its use should be restricted to local applications alone. But it was finally determined that the hospital should not rest on any irrational thought, but stand as an exponent of the most advanced scientific ideas on the temperance question. Hence, alcohol has been discarded as an *active* medicinal agent. The use of all fermented and distilled liquors is prohibited. Tinctures and extracts, where alcohol has been used as a solvent, have been retained, as it does not enter into their preparation in sufficient quantities to be considered an *active* medicinal agent. The basic principles upon which this institution rests may be formulated as follows:

1. Alcohol is a poison.
2. When taken into the system, it is not assimilated, but passes the round of the circulation, and is finally thrown off through the organs of excretion, unchanged.
3. While passing through the body it disturbs the various physiological processes, and in this way lays the foundation for disease.
4. It does not stimulate or strengthen, but it depresses and weakens.
5. As it is not assimilated, it cannot be a food.
6. As it disturbs every physiological process, it cannot be a medicine.
7. There is no disease afflicting the body, that cannot be more successfully treated without than with the use of alcohol.

Everything pertaining to or connected with

this institution rests upon this platform. The nurses of the training school are instructed in these principles, and every member of the medical staff is expected to maintain and practice them, not only in the hospital but in private practice.

The work so far done by the hospital has not been large, but it is flattering. There are only accommodations for twenty patients. It is not endowed, but strange to say, and contrary to the history of most hospitals, it is not in debt, but more than pays expenses. The House Physician's Report for last year shows that during that period, one hundred and forty patients have been treated, and ninety-eight surgical operations performed, with the phenomenally low mortality of only 5 per cent. Owing to the necessity of making the institution self-supporting, the work so far done has been largely surgical. In no instance, either surgical or medical, has it ever been deemed necessary to administer alcohol. No accidents, or conditions approaching an accident, have ever occurred during the administration of an anæsthetic. Some five years of surgical work without the use of alcohol convince me, that many of the sudden deaths which occur while giving anæsthetics, are due to the unnecessary administration of alcoholic liquors during or previous to the operation. It would be interesting and undoubtedly instructive, if the statistics of this subject could be collected and published.

I thoroughly believe that a grave and frequently fatal mistake is made in debilitated cases, by the administration of alcohol preparatory to the performance of severe surgical operations. The patients in these instances, are compelled to endure both the operation and the depressing effect of the alcohol on the vaso-motor nerve centres. A very typical instance came under my observation in the hospital a few weeks ago, in a case of ovariectomy. The patient was a woman of 35, from the country. Owing to a mistaken diagnosis, the operation had been neglected till she was reduced to an extreme degree of emaciation. In this debilitated condition, and almost pulseless, she was placed on the operating table. Under the old *régime*, half a tumblerful of brandy would have been given. Two grs. of quinine had been administered four times a day for two days previous to the operation. She rallied without the slightest symptom of shock, and made a rapid recovery.

Among the operations performed in the hospital during the last year, I may enumerate hæmorrhoids, trachelorrhaphy, tracheoperineorrhaphy, Alexander's operation, fistula in ano, varicocele, schirrus of the breast, amputation of leg, laparotomy, removal of polypus of the womb, ovariectomy, and numerous minor surgical operations. The diseases treated have also been varied, as

septicæmia, peritonitis, chronic cystitis, paraplegia, tuberculosis, pneumonia, ovaritis, morphine habit, chronic alcoholism, Bright's disease, typhoid fever, intermittent fever, etc.

With the small beginning that we have made and the success we have already attained, we feel encouraged to pursue the work. The lesson already taught has been sufficiently convincing to impress the most skeptical that alcohol is not only unnecessary as an active medicinal agent, but that, in a majority of cases, it is an actual hindrance to the recovery of the patient. Slowly but surely, every year, this great truth is being impressed on the minds of the medical profession.

Says Herbert Spencer, "All great mental changes take place with deep laceration of feeling." This will be verified during the conflict that is arising in regard to the use of alcohol as a food and a medicine. Every foot of scientific advance will be contested by ignorance and fallacious argument. Ideas and beliefs that have been for centuries fed by passion, appetite and superstition, cannot be eradicated in a day. The process must be one of gradual education. Slowly but surely, the evolution of thought will accomplish this work. Truth, pure and uncompromising, will ultimately prevail. The present battlefield of the temperance fight now lies in the medical profession. If alcohol *is* a food and a medicine, all the eloquence and logic of modern thought cannot save mankind from intemperance. For man will never be able to take these liquids moderately and without harm. If alcohol is *not* nutritious, and serves no purpose as a therapeutic agent, then the world should be so instructed and its promiscuous use abandoned.

Surely the destruction that is now going on from the use of alcoholic liquids, deserves the immediate attention of the medical profession.

This must be the most potent factor in the production of human suffering. The danger that threatens the civilization in which we live is, that it may "crumble and fall from the corroding action of alcohol on the nerve and brain centres." The truth of our previous assertion must be demonstrated, and to do this, a hospital is necessary. The National Temperance Hospital is dedicated to this work. Its Board and Medical Staff send a greeting to the National Medical Temperance Convention.

SUBCUTANEOUS INJECTIONS OF CAMPHORATED OIL.—According to B. Alexander, of Berlin, hypodermatic injections of camphorated oil have a cumulative effect, causing, after the fifth injection, pains in the head. When used in diseases of the respiratory organs, in small doses, it has antipyretic effect. In heart diseases, where digitalis does not seem to be of further use, camphor injections will enable the action of digitalis to be resorted to again.

ADDRESSES.

AN ADDRESS DELIVERED AT THE OPENING OF
THE SECTION OF THERAPEUTICS,*At the Annual Meeting of the British Medical Association, held in Bournemouth, July, 1891.*BY WM. VICARY SNOW, M.D., LOND., M.R.C.P.,
Senior Physician to the Royal Victoria Hospital and the National
Sanatorium, Bournemouth; President of the Bournemouth
Medical Society.

Gentlemen:—On behalf of my medical brethren resident in Bournemouth, as President of this Section, I have a pleasant duty to perform, to give a most hearty welcome to our foreign guests and all members of the British Medical Association, on this their first visit to our town. Allow me also to thank the Council of the British Medical Association, for the honor conferred in allowing me to address you from the chair of this meeting.

In consequence of our more accurate knowledge of disease, and especially of those affections attended by febrile phenomena, since the introduction of the clinical thermometer, much progress has been made in therapeutics. We have been able to more correctly estimate the action of remedies, not only in health, but in disease, and hence treatment has become more scientific and rational. It is not, however, too much to expect that the greatest triumphs of the future may arise from the new study of animal chemistry and bacteriological research.

In specific disease we have learnt that it is not only the microorganisms present which have to be considered, but that it is probable the chemical changes they set up play a most important part in causing the phenomena of disease. It is well established that certain zymogenic organisms give rise to a chemical product inimical to their own growth, and when of a certain strength sufficient to stop the process. The mortality from consumption is now, in England, not more than one-half of that existing during the first fifty years of this century, while the death-rate from this disease has increased in many countries. This grand result has been obtained by improved methods of treatment, sanitation, improvement in the workshops and dwellings of the laboring population, and especially by the subsoil drainage of towns. In the year 1882 the tubercle bacillus was discovered, and it was proved that consumption could be produced in animals by the inoculation of a pure cultivation of it. Briefly, it has been demonstrated that without the bacillus no lung affection can be considered consumption. True, however, as this statement is, to my mind it is not sufficient to account for the production of the disease. The bacillus and its spore have great vitality, and must be, as a rule, present in our houses, and especially in our hospitals for consumption. Further, an appreciable percentage of animals slaughtered for food are said to be tuberculous, nor is the bacillus destroyed by imperfect cooking. Granted that it has been proved that this disease is occasionally produced by contagion, yet we do not find those employed in our consumptive hospitals more liable to infection than the ordinary population. I must hold, then, that the bulk of mankind are proof against the attacks of the bacillus, and that it can only fasten on the tissues of those weakened by bad hygienic or climatic conditions, repeated lung congestions, or hereditary taint. So far no drug has been proved capable of destroying in the human body the tubercle bacillus, or arresting its development by action on the diseased tissues in which it finds its pabulum. For years I have used carbohc acid and other inhalants, and found decided benefit arise in soothing cough and other symptoms, but no evidence whatever could I discover of their exercising any influence on the growth of bacilli. In cultures, a moderate advance above the natural heat of the body prevents the growth of the bacillus, and it was assumed that consumption

might be cured by the inhalation of heated air; but in practice it was found impossible to raise sufficiently the temperature of the air in the lungs, and this treatment has now fallen almost into oblivion. The insufflation of sulphuretted hydrogen into the intestines has entirely failed, nor has any drug yet been proved to be able to influence the growth of the bacillus when injected subcutaneously, but trials are now being made in this direction.

At the International Medical Congress last year, it was announced by Koch that a remedy had been discovered which conferred on the animals experimented on an immunity against inoculation by the tubercle bacillus, and which would arrest tuberculous disease, and that the remedy would be tried on human beings. In spite of all precautions exaggerated reports of the value of the remedy were propagated, and the public impatience, and, it is even hinted, Government pressure, induced him to make a partial disclosure of the nature of the remedy and the method of its use before any sufficient experience had been obtained of its effects on the human body.

When this discovery was first announced it was compared to that of vaccination and Pasteur's treatment for hydrophobia, but several very marked distinguishing points induced most reflective minds not to anticipate equally good results.

Jeuner was dealing with small-pox, a disease as a rule occurring only once during life, and rendered the system incapable of an attack by the substitution of a form of the same disease weakened by transmission through the cow. In hydrophobia the remedy is introduced into the system after the contagion, but before the symptoms of the disease have manifested themselves. In Koch's method the remedy is not applied until after the disease is established, and can only arrest its further progress, but cannot repair the damage already effected.

The public excitement was increased by a not unnatural mistake of the daily press in calling the remedy a "cure for consumption," instead of a "new remedy," for the treatment of that affection. The medical profession were also greatly impressed by the immediate beneficial effects produced on some surgical affections, and notably on lupus; sufficient time had not then elapsed to prove that the results were not always of a permanent character. Hence, even before the manufacture was perfected (and I have reason to believe that the first tuberculin produced more serious symptoms than supplies subsequently sent out), a treatment requiring the greatest care was initiated in the middle of almost the most severe winter of the century, and mainly in the foggy, crowded, and in many instances insanitary large cities of Europe.

One result only could follow: the unreasoning belief of the multitude in a new remedy was disappointed, cases of mischief from its use were reported, statements against it, often I believe beyond what science would justify, were made, and a danger existed, and still exists, that a discovery, which at any rate merits a fair trial, may be discredited and even consigned to oblivion from the rash way in which it was introduced. In consumptive people, even when not much tissue is affected, a small injection of tuberculin—as little as 0.002 cubic centimetre—may cause intense febrile reaction, and, from the frequency with which stained expectoration has been noted, we may infer that active congestion is set up wherever tuberculous tissue exists, whether in the lungs, kidney, or brain membranes; hence the danger of its use where complications either exist or, as in the very young, may be feared. Would any physician, if he had the choice, wish to treat a case of pulmonary phthisis in the air of a large city, during the time of smoke and fogs, much less put him on treatment which, for the time at least, must produce considerable febrile reaction? It appears to me that, instead of in Berlin, the treatment should have been initiated in good country air, and

when completed the patients should have been removed to an approved climate.

Before the injection of tuberculin can be adopted as a recognized method of treatment for consumption, the following question must be answered in the affirmative: Can this treatment be carried on with reasonable safety? In very weakly patients and those with extensive and advanced disease, such a treatment must be attended with risk, and it is not surprising to hear that fatal results have directly followed the injection of tuberculin. The ten cases treated at Ventnor, the similar number treated in the Sanatorium, coupled with the experience of Dr. Coghill at Ventnor in private practice, and my own, inclines me to believe that tuberculin may be safely used in cases judiciously selected, under favorable circumstances. I will now, as briefly as possible, call your attention to the only three cases I treated in the Sanatorium in the year 1890, and I do so because I have been able to trace the results over a period of seven months from the first injection.

E. M. was admitted on November 6, 1890. She had lost three sisters from consumption, and other relatives, had been ill more or less for three years, and had had one attack of hæmoptysis. Her afternoon temperature ranged from 90 to 100°. The expectoration measured 3ss. was muco-purulent, and contained bacilli. The resonance was imperfect at the apex of the right lung, and the respiration bronchial; the left lung was affected to a less extent. The treatment was commenced on December 6th and completed on January 30th. Twenty injections in all were given. The patient had lost 4 lbs. in weight in the previous fortnight, and lost 6 lbs. more during the first four weeks of treatment. On January 30, the patient had very little cough or expectoration; did not react to 0.01 cubic centimetre, but bacilli were still present. She continued to steadily improve, and left the hospital on April 21, having lost all cough and expectoration and gained 12 lbs. in weight from the lowest point. Her temperature was normal, and, on examination, the physical signs were found to have improved. The last expectoration obtained contained no bacilli. She had been previously living at home without occupation; she now writes—July 2nd—that she has remained perfectly well, and has entered domestic service as nurse. As the patient was losing weight before, and for a month after, the commencement of the treatment, and had an exceptionally bad family history, and, as no symptoms of relapse have been observed up to seven months from the commencement of treatment, I think we may fairly claim that the disease has been arrested; no case of consumption can be considered cured until all symptoms have ceased for two years.

A. D. (dressmaker), 18. Admitted November 3rd. Duration of illness nine months. A sister consumptive. Had gained 2 lbs. in weight before treatment commenced on December 6th. Beyond slight dulness and prolonged expiration at the left apex, no physical signs existed; the expectoration was scanty, and contained a few bacilli; evening temperature, 99.8°. Eighteen injections were given but, in consequence of the severity of the reactions (104.8°) the amount was not carried above 0.005 cubic centimetre. January 30.—Patient feels perfectly well; has no expectoration or cough, and has gained 5 lbs. Physical signs unchanged. She continued to improve, and gained from the commencement of the treatment 12 lbs., and was discharged on April 22. She writes, July 2nd: "I think I am about the same weight as when I came home, having neither cough or expectoration, nor do I perspire at night; I am, also, able to follow my employment without difficulty." You will observe that tolerance of the tuberculin could not be established, and that the amount of the disease was very slight. It is quite possible that to the change of climate and rest from work the improvement is due.

W. H. (footman), aged 23. Three years before pleurisy with effusion, expectoration 3ss.; muco-purulent,

containing numerous bacilli. Considerable consolidation existed at the apex of the right lung, weak breathing was noted at the base and dry friction in the right axilla. The left lung was only slightly affected at the apex. Sixteen injections were given from December 4 till January 17, and then discontinued in consequence of a very severe attack of dyspnoea. Three times the expectoration was stained with blood, six times dyspnoea was noted. The febrile reactions were moderate. The treatment was resumed with a fresh supply of tuberculin on February 17, and continued until on March 19, no reactions followed the use of 0.01 cubic centimetres. The patient was discharged on April 9. He was feeling much better. The percussion note had improved and the breathing became more vesicular. The temperature was normal and the cough and expectoration slight. No bacilli could be found in the expectoration. He gained 4 lbs. in weight before the treatment was resumed, and during it lost 3 lbs. He shall speak for himself as to his after-progress in a letter to the lady superintendent, June 12:

"MADAM,—I am very pleased to tell you I have improved in health very much since I left the Sanatorium. I have gained in weight seven pounds, and I have been in work a fortnight now, and able to do it with pleasure, and feel it only right for me to let you know the good I got at the Sanatorium through Dr. Koch's treatment. I have hardly any cough, and I get no pains at all. I am pleased to say I am going to the Cape in July, so as to get out of England before the winter comes on, as my doctor thinks the fogs might strain my chest too much. I am pleased to tell you he gave me a good account of myself; he said of all the cases he had seen, mine was the best."

Subsequent reports confirm the improvement in this case. I will now allude to the result of the only three cases I ventured to treat after softening had taken place.

E. M., 44, had a slight attack of hæmoptysis five years since; softening had commenced at both apices. First injection February 6, 1891; discharged May 12. This patient improved in strength and gained in weight 16 lbs., but I could detect no signs of improvement in the lung condition.

E. K., 22. Two months since a slight attack of hæmoptysis. In this case, also, softening had commenced on both sides, and a small cavity existed at the right apex. First injection February 24; discharged June 15; gain in weight, 10 lbs. The improvement in the physical signs was slight. Numerous bacilli were found in the sputum.

These two patients, when admitted, were almost normal in temperature, and I am inclined to think much of the improvement in weight was due to rest from employment, better food, and change of climate. I am fortified in my opinion by the result of the third case.

C. H., 21, had been resident in Bournemouth and under observation two years, and had done clerical work at the Sanatorium. The treatment was carried out at his home without difficulty, although before, and when he at first came to Bournemouth, hæmoptysis had been a feature in his case. The physical signs improved, but he did not gain weight.

The treatment was carried out with the antiseptic precautions recommended, and no evil consequences followed the punctures. The patients were placed under the best hygienic conditions possible—kept in bed during the febrile reactions, and fed mainly on a milk diet. It may be asked, What unpleasant symptoms were observed, and is previous hæmoptysis a bar to the treatment? Although stained expectoration was frequently noted, it was never sufficient to cause anxiety, and never more than a temporary intermission of the treatment. Pain in the lungs, and especially where old pleurisy had existed, often occurred; in one case severe dyspnoea was observed. I have already mentioned that it did not recur when the treatment was continued with the fresh tuberculin.

Limits of space debar me from entering on the pathology of the remedial effects of the treatment, and I am pleased to tell you I have had no opportunity of studying post-mortem appearances.

Stimulated by Koch's discovery, the inventive faculty of the profession has been at work, and, as I write, new methods of treatment are under trial, especially in Paris. May they be tried under more auspicious circumstances, and not prematurely introduced. Whether this discovery be a success or a failure, I feel that a line has been indicated pregnant with grand results, not only for the arrest of consumption, but also for the treatment of other diseases.

BOOK REVIEWS.

SURGICAL BACTERIOLOGY. By N. SENN, M.D., Ph.D. Second edition. 8vo., cloth, pp. 265. Philadelphia: Lea Brothers & Co., 1891. Chicago: A. C. McClurg & Co. Price, \$2.

This second edition of Senn's Surgical Bacteriology has been changed from the former edition by division into chapters, and by bringing the literature of the subject to the date of the revision, viz., March, 1891. The work is, therefore, at this time, the most complete of any. Prof. Senn's acquaintance with the languages of Europe has enabled him to make a complete digest of the European literature bearing upon this subject, and his untiring industry caused him to glean all that is valuable. His own original experiments, while doubtless giving color and direction to his thoughts, are seldom put forward, but the work stands just now as the best practical review of the literature of surgical patho-bacteriology in existence. The duration, however, of this kind of work is necessarily short. The vast and rapid changes that are going on in bacteriological discovery, heralded from week to week in the medical journals, and by publications direct from the great laboratories, render a book on bacteriology antiquated while yet warm from the press, and Prof. Senn will find that his classical book of experimental surgery will be quoted long after the "Bacteriology" has been raised to a top shelf in the library. His development of the hydrogen gas test and decalcified bone plates will perpetuate his unchallenged supremacy in his especial field, and compilations, however temporarily useful they may be, will not materially add to it. There are many compilers, but the investigator must be born with natural qualifications for the work, and hence they are few. But we must no longer digress, however tempting the theme. The book under consideration, strictly speaking, covers the essential portions of surgical pathology, and whoever, in this year of our Lord, 1891, would have a clear and comprehensive digest of the existing European literature of surgical patho-bacteriology will find it in this

volume. The illustrations are inserted on separate sheets from the text, and are beautifully executed. The book is well worthy of the time-honored medical publishing house that issued it, and the fact that it has passed to its second edition is the highest testimony of its great merit.

THE SURGICAL TREATMENT OF WOUNDS AND OBSTRUCTION OF THE INTESTINES. By EDWARD MARTIN, M.D., and H. A. HARE, M.D. 8 vo. cl., pp. 165. Philadelphia: W. B. Saunders. 1891. Price, \$2.

This little volume is the essay which received the Fiske Fund prize at the annual meeting of the Rhode Island Medical Society, held at Providence, June 12, 1890. The essay is divided into fourteen well-written chapters, which state in the best form the teachings of the day in regard to the subject. The authors also furnish a table of cases of cœliotomy for gun-shot wounds of the abdomen, and a careful summary of the tables. The chapters include the subjects of Intestinal Obstruction due to Congenital Malformations, Intussusception, Internal Strangulation, Volvulus, Obstruction from Foreign Bodies, Intestinal Paralysis, Chronic Obstruction and Peritonitis. There is a chapter on Diagnosis and on Wounds and Rupture. The tables are marred by bad proof-reading of the names of surgeons whose cases are quoted. Among the Americans thus pilloried we notice the following: W. S. Bull, instead of W. T. Bull, four out of five times; G. Hamilton instead of J. B. Hamilton and Kinlock instead of Kinloch. We trust that the European surgeons have met a better fate at the hands of the essayists.

Notwithstanding the carelessness here noted, the authors have not only produced a very readable book, but one of extreme value, and the practiced hand of Dr. Hare is everywhere manifest in the "make-up" and literary character of the book. One of the doctor's ardent admirers recently said that he was of impression that Dr. Hare had an open contract to produce seven-eighths of the literature of the present decade, without regard to subject; and it must be admitted that if the allegation is true, medical literature will be the gainer, in clearness of expression, graceful sentences, and conciseness of statement. The book under review is an example in these respects which Americans can well afford to compare with similar works abroad. We notice here, without, however, subscribing to their conclusion, the strongest protest against surgical interference and intestinal suture in cases of gun-shot wounds of the intestine, and the authors claim that the results of cases treated expectantly are as good as those by laparotomy. They cite two instances where Senn's hydrogen gas test has failed to show the perforations.

Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to
JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,
CHICAGO, ILLINOIS.

All members of the Association should send their Annual *Dues* to the *Treasurer*, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

BY-LAW IV.—THE PUBLICATION OF PAPERS AND
REPORTS.

No report or other paper shall be entitled to publication in the volume for the year in which it shall be presented to the Association, unless it be placed in the hands of the Board of Trustees on or before the first day of July. It must also be so prepared as to require no material alteration or addition at the hands of its author.

Authors of papers are required to return their proofs within two weeks after their reception; others lie they will be passed over and omitted from the volume.

Every paper received by this Association and ordered to be published, and all plates or other means of illustration, shall be considered the exclusive property of the Association, and shall be published and sold for the exclusive benefit of the Association.

The Board of Trustees shall have full discretionary power to omit from the published *Transactions*, in part or in whole, any paper that may be referred to it by the Association, or either of the Sections, unless specially instructed to the contrary by vote of the Association.

CHEMICAL ANALYSIS OF FOODS.

One of the first of the artificial foods for infants, was that of LIEBIG. It was made by a master hand, so far at least as its chemistry was concerned. It contained the exact amounts of albumin, sugar, fat, and salts necessary for the nutrition of the child. But an extensive use proved that it failed in its object. The lesson which it teaches is only slowly gaining ground. That lesson is, that the animal organism requires something more for its maintenance than so much albumin, so much fat, and sugar, and mineral matter. It requires that these substances shall be of such kind, and in such form that they can be both digested, and assimilated. The examination of the food of the properly nourished individual, shows that he requires for instance, a given amount of proteid. Certain foods contain the proper amount of proteids. It is thereupon assumed that these foods will answer the requirements of nutrition, which does not always happen. This is not the first nor the only time that physicians have been misled by a name. It is a little difficult to realize that a name is only a convenient tag, and does not always reveal completely the contents of the bundle to which it is

attached. What is a proteid? Something which has certain definite chemical reactions. Certain differences in reaction enable chemists to separate in a crude, but convenient way, the proteids into several classes. But the separation of the proteids into classes, and indeed the very recognition of the proteids themselves, is by no means wholly artificial, and the several tests for these purposes give no idea whatever of the structure of these substances.

The various proteids certainly are available as foodstuffs, but under what conditions each is most effective as a nutrient, is not known. Moreover, this question is a biological one, and, at present at least, far beyond the ability of chemistry to answer. It should therefore be clearly realized, that the term proteid is a purely chemical one, and gives name to a group of substances which answer the requirements of indirect, almost artificial chemical tests, and that the taking of the word in the broader biological sense, and making practical applications as such, is liable to terminate in disappointment, as in the LIEBIG instance.

Physiologists have shown conclusively that common salt is the only mineral substance, iron possibly excepted, which has a direct food value. All other so-called mineral elements are available for food only when they form constituent parts of the complex molecules of the various organic foodstuffs. For instance, it has been attempted to supply the deficiency of lime in the bones in rickets, by the administration of calcium phosphate, but without success. The animal organism is unable to build calcium phosphate into bone tissue. It must receive its calcium and its phosphorus in some other combination. This combination, to be assimilable, must be an organic one, such as is found in the yolk of the egg, to give a single example. To destroy a cereal by heat to obtain from the ash the phosphate produced, is an illogical procedure. Identically the same products can be formed in the laboratory at much cheaper rates. The condition which made this ash available as a food, was its existence in organic combination in the grain, and this availability was destroyed with the destruction of the grain.

At a meeting of the Association a few years ago, the writer heard a well-known member remark to a food manufacturer, who was demon-

strating by chemical tests the large amount of albumin present in his beef extract, that it was quite immaterial how much albumin it contained, that the chemical test was worthless, that the only test of the value of his food was the clinical observation of its assimilability. This seemed at the time a little severe to the writer, who was still impressed with the equivalence of chemical and nutritive terms. To-day he can heartily endorse the observation.

It is not intended to deny that chemical analysis is of some value in assisting in the selection of foods, but one must be guided in making these analyses by a clear and full idea of their scope, and their limitations. Ultimate analyses of foods are of very little use in determining the nutritive value of these substances, and are often very misleading.

THE PATHOLOGY OF QUININE AMAUROSIS.

DR. DE SCHWEINITZ, of Philadelphia, has contributed in the *Ophthalmic Review*, February, a paper on the results of some experiments undertaken by him to determine the lesion of blindness from quinine. He administered the drug by the hypodermic method in a series of six dogs, using doses varying from 1 grain to 6 grains to each pound of the body-weight. The result of this procedure was a loss of vision in from three to fourteen hours—the exact interval before the onset of blindness not being ascertainable; this symptom was also commonly accompanied with other general disturbance within the same interval of time. In one instance the loss of vision remained practically complete for a period of twenty-nine days in consequence of a single dose of $3\frac{3}{4}$ grains to the pound of body-weight. The ophthalmoscopic appearances were essentially like those found in man having amaurosis from quinine. In every case the pupil was immovably dilated. Each dog was killed—if he did not die from the effects of the drug—and a microscopical examination was recorded of the eyes, optic nerves, chiasma and occipital lobes. No gross lesion, with one exception, was found in the nerve, disc or retina; in the exceptional case there was in one eye a decided dilatation of the blood-vessels, with white thrombi in the smaller veins, while the central vein was plugged with a clot. A dilatation of the vessels, to a

minor degree, was observed in the optic disc in some other cases. No marked lesion was found when examining transverse sections of the nerves, except at times some œdema was observed and a slight apparent increase in connective tissue. It is worthy of note, however, that even in dogs blind from quinine for a month and more, there was no appearance of atrophy of the nerve fibres, nor in the earlier stages was any neuritis discoverable. No abnormal change in the chiasma was observed in any instance. Sections of the cuneus showed in every instance a remarkable dilatation of the pericellular lymph-spaces, with degeneration of the protoplasm of the cell, and the lesion was most marked in the case of the dog that was longest blind. The author does not assert that he has in this lesion discovered the true pathology of quinine blindness, for the reason that he appreciates the room for imperfections in microscopical studies of this nature, but he believes that his observations will strengthen the position of those who have located the lesion in the optic nerve somewhere between the chiasma and the eyeball, and that œdema enters into the question as being a part of the morbid alteration. It is also well to bear in mind that the peripheral circulation may possibly be affected, as instanced by that one exceptional case where a clot was discovered in the central vein. This was, without doubt, an extreme instance, and should a like change take place in the human subject, any chance of recovery from blindness would be nearly or quite hopeless.

BEER VERSUS BRANDY.

The manufacture and consumption of fermented liquors is sometimes urged in the interests of temperance, on the ground that it diminishes the use of distilled spirits. That such is not necessarily the case seems pretty clear from the statistics of the countries in which wine and beer are most largely consumed. The *Irrenfreund* has lately called attention to the alarming prevalence of drunkenness in Germany. The consumption of beer, throughout the German Empire, is a little less than half a pint per diem for the whole population—men, women and children. Large quantities of wine are also consumed. There is probably no country where the conditions are so

favorable for temperance, on the theory above alluded to. Nevertheless, Germany ranks third in the consumption of distilled spirits, consuming eleven litres, or twenty-three and one-fourth pints per capita of the total population. Denmark consumes twenty, and Russia twelve litres per capita. Even if it be granted that the consumption of such an amount of wine and beer in Germany is in itself an unmixed benefit, it is not evident that the more deleterious forms of alcoholic indulgence are suppressed by it to any great extent.

Wine has been, from time immemorial, the national drink of France, as beer is of Germany, but the consumption of spirits is steadily and rapidly increasing in that country. The total amount consumed in 1890 is reported by the Minister of Finance at 37,395,000 gallons. In the department of the Lower Seine it amounted to three gallons per capita of the population.

Vienna is celebrated for its beer, and is in the midst of a wine-growing country. Of 516 men admitted to the city insane asylum in 1888, 143 are reported to have become insane exclusively through alcoholism, and in 93 more cases it is reckoned as a contributing cause. On the whole, it seems as if the friends of temperance would have to look in some other quarter for allies in the suppression of drunkenness.

GRAFTING CANCER IN THE HUMAN SUBJECT.

At a recent meeting of the Paris Académie de Médecine, CORNIL reported two cases of successful grafting of malignant growths in the human being. He stated that the first case had been communicated to him by a foreign surgeon, whose name he withheld, and whose act he did not justify. This surgeon removed from a woman, a breast which was the seat of an enormous tumor; then while the patient was still under the influence of the chloroform, and of course without her consent, cut a small section of the tumor and inserted it under the skin of the opposite healthy breast, using the strictest antiseptic precautions. The wound healed by first intention and for the first few days nothing was noticed at the site of the graft, but soon an indurated nodule developed and in two months, having grown to the size of an almond, was removed by the same surgeon.

Both tumors were examined by CORNIL, who

found them to be sarcomata and identical in structure. The ingrafted portion of the first tumor had become a part of the healthy breast, vessel anastomoses had occurred, its cells had penetrated into the healthy adjacent tissues, and its rapid growth was indicated by the karyokinesis of the cells. Shortly afterward the patient died of some acute intercurrent malady, and the autopsy, which was made with great care, revealed no trace of sarcoma in any portion of the body, neither in the lymphatic glands, internal organs, or the spongy tissue of the bones.

In the second case, a portion of a tumor removed from a breast was in a similar surreptitious manner inserted into the healthy breast of the patient. This tumor proved to be an epithelioma. The second graft, like the first, produced no inflammatory reaction, but later at the site of its insertion a nodule developed. The patient declined to have the second breast removed, and disappeared from the surgeon's observation.

It is pleasing to note that the French Academy at the close of the reading of this paper, expressed only its stern disapprobation of the methods employed, and by silence refused to discuss the scientific aspects of the cases. The indignation was not confined to the Academy, but also found vent in the public press, and CORNIL felt compelled to defend himself in a letter to *Le Temps*, in which he defends the publication on somewhat remarkable ground. He compares it to the breaking of a bridge in a railroad accident, the causes for which are sought in the midst of the calamity. He further instances the well known case of Alexis St. Martin, whose accident gave DR. BEAUMONT an opportunity to investigate the function of the stomach. From these he urges that while we must condemn the surgeon who did the work, we ought not to ignore whatever the unfortunate occurrence may teach us. This is pure sophistry. It ignores the grand object of medicine, which is to relieve suffering, not to acquire abstract knowledge. And questions which require for their solution the infliction of needless suffering on human beings, must wait until a proper opportunity for their solution presents itself. We cannot afford to stultify our profession, whose great boast, and whose legitimate boast, is its humanity, by such criminal acts.

Putting humanity entirely in the background, such experiments can not be defended even in the

name of science, for they are not scientific. They prove only that the implantation of a sarcomatous or epitheliomatous mass in persons already suffering from the corresponding disease is capable of causing a local sarcomatous or epitheliomatous growth. This does not prove that these growths are infectious, for who can say that some other form of irritation in these same individuals would not have caused like results? The gain to science by these experiments is decidedly problematic, at most it is insignificant, and utterly incommensurate with the cost at which it was obtained. We could far better have afforded that such experiments should have forever remained untold, than have gratified, perhaps to some extent justified, the individual who made them. If, however, the storm of indignation which has been aroused shall deter others who might have in view, in their zeal for science, similar unjustifiable experiments, CORNIL's publication will have had a real, though unexpected value.

It remains to be said that since the Parisian affair, PROFS. HAHN, and VON BERGMANN of Berlin, have both been openly charged, by an officer of the German Government, with having inoculated cancer in the healthy human being. Their reply has not yet come to hand.

A CASE ARBITRATION.

Last week we took occasion to note the result of a recent trial for malpractice, and on account of its fairness and justice published in full the decision of the Appellate Judge who heard the case. This week we note another instance in which suit was brought against one of the most prominent physicians in this city, and by consent submitted to a board of three physicians chosen to act as arbitrators. A large amount of testimony was heard, the trial occupying an entire week. In the finding the arbitrators unanimously decided that the defendant was not guilty as charged by the plaintiff. The plaintiff alleging that the defendant had improperly diagnosed and treated the case. The arbitrators found the defendant's diagnosis to be correct and the treatment in perfect accord with the laws of medical science.

The method of settling disputes by arbitration is one commonly adopted by merchants and others engaged in the common business affairs of

life, and is highly satisfactory to all concerned except the attorneys. This is the first instance within our knowledge where this plan of settlement has been adopted in a case where an individual believed himself unskilfully treated by a physician.

Such a method of settlement should always be resorted to when it is possible to do so, and no case allowed to be brought before any other tribunal unless the plaintiff give bond for all costs incurred by the defendant where the case is decided in defendant's favor.

LIFE INSURANCE AND SYPHILITIC "RISKS."

MR. JONATHAN HUTCHINSON has published a paper in the *London Practitioner* on the "Modern Treatment of Syphilis," in the course of which he considers some of the more important relations of syphilis and life insurance. He states that he had recently been requested by a life insurance company to formulate a code of rules for the guidance of its examiners when considering the acceptance or rejection of applicants for insurance who have had syphilis. His advice on this subject was for the most part favorable to the applicants; with this exception, however, that he would decline those persons who at the time of their presentation, shall be undergoing the active development of secondary symptoms. These applicants, he advises, should be told to wait until these symptoms had disappeared. He based this counsel on the fact that it is always desirable to know how well or how ill the syphilitic patient sustains the specific treatment proper to the second stage of the disease, and also how willing and attentive he may be to follow out the directions of his physician. Mr. HUTCHINSON holds that an insurance company might make a profitable business out of syphilitic risks accepted in the early stage of the disease and taken at the ordinary rates, for he has found that the threatened life is often a long one. In his experience such syphilitic persons appear quite as likely to attain to length of days as others who have not been syphilitic. In the cases of those who present themselves free from symptoms, but who have the history of a former attack, the advice is that they be not refused, provided that they have not definitely become the subjects of the tertiary lesions of the disease, or have not, owing to

idiosyncrasy or inadequate treatment, had a prolonged seige of secondary symptoms. But even among these there are not a few who would be regarded by Mr. Hutchinson as eligible risks at ordinary rates.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

In the New York letter published in *THE JOURNAL* of July 25, by a slight mistake in the placing of quotation marks, Dr. Morton is credited with some remarks on the return of pauper and diseased immigrants which were not made by him, and the quotation from Dr. M. should end with the paragraph referring to the colour for the insane at Gheel.

Since that letter was written, the Treasury Department at Washington has issued a circular calling the attention of all corporations and others engaged in bringing alien immigrants into the United States to the laws of this country regulating immigration, as amended in March last. In this it is stated that the evident disposition of many steamship lines, under the pressure of sharp competition, to gather up in Europe and bring to the United States all who, with or without the aid of others, can pay the now trifling sum of a steerage passage—regardless of their character or condition and regardless of our laws—compels on the part of the Government a close scrutiny, and the adoption of more comprehensive measures than have hitherto seemed necessary. While it is the purpose of the Government to enforce these statutes in their letter and spirit, it is desired that as little discomfort and distress as possible result to persons affected by the immigration laws. With this in view, it is important that persons of the prohibited classes be prevented from leaving their homes and crossing the sea, only to be sent back on their arrival here. It is wrong that either the greed of some steamship companies, the mistaken kindness of friends, or the wish of many foreign communities to be rid of burdens properly theirs, should be permitted to result in this useless cruelty. So far as possible, the sifting process should be applied at the beginning, not at the end, of the long journey.

The circular also gives notice that, inasmuch as some steamship lines, in order to increase their carrying capacity, have recently disregarded the provisions of the laws of the United States requiring a certain allowance of cubic air space to each steerage passenger, hereafter more thorough inspections will be made of all steamships engaged in bringing immigrants here, and that the penalty for violation of the law in this respect will be rigidly enforced.

It is a fact of great interest as regards the cause of medical education in New York that from this time on the salaries of the faculties of both the medical department of the University of the City of New York and of the College of Physicians and Surgeons are to be fixed

sums, and no longer dependent on the number of students matriculating. On July 1 the College of Physicians and Surgeons became, under the authority of the legislature, a part of Columbia College, and will in future be administered as such, the medical department thus made an integral part of the university system, instead of having a merely nominal connection with the central collegiate institution. It is also announced that, as has been the case for some time as regards the College of Physicians and Surgeons, a three years' graded course of study is now to be obligatory at the University Medical School. Another innovation at the latter institution is the introduction of the recitation system in place of the didactic lecture during the first and part of the second year.

The circular of information just published by the College of Physicians and Surgeons states that the large accessions to its teaching force, notably in the department of anatomy and in the physiological, pathological and chemical laboratories, permit the realization, to a degree hitherto quite impossible, of the great opportunities for instruction and research afforded by the excellence of the dissecting rooms, the laboratories and apparatus. The college building proper covers an area of no less than 15,428 feet, and the Vanderbilt Clinic, which is connected with it by a covered way, besides a very completely equipped dispensary department, contains numerous small rooms for the direct practical teaching of diagnosis and treatment to groups of students, and a theater for clinical lectures which accommodates an audience of nearly four hundred. During the year 1890, 120,000 patients were treated at this institution. The Sloane Maternity Hospital, also upon the college grounds, contains thirty-nine beds, all of which, by reason of its large endowment fund, are free in perpetuity. The obstetric service here is under the direction of the professors of midwifery at the college, the instructor in obstetrics being the resident physician; and the members of the graduating class are each required to attend a certain number of cases of labor in the hospital. The students of the third year are divided, at the beginning of the term, into classes of six, each section remaining on duty for one week, and during this time they are furnished with rooms in the dormitory free of charge. These lodgings are upon the college grounds, and are connected with the hospital by electric wires. Bedside instruction is given by the resident physician during the week, and at its close an examination is held in the hospital by the adjunct professor of obstetrics on the work of the week. From the time of the opening of the hospital to May, 1891, a period of three years and four months, 1,250 deliveries took place at this institution.

Owing, no doubt, in great measure to the continued cool weather, the health of the city still remains unusually good for this season of the year, the number of deaths being much smaller than the average of past years. During the week ending July 25, 947 deaths were reported, which represents an annual death-rate of 29.34 per thousand of the estimated population of the city. Considerably more than one-half of this total mortality, however, was in children under five years of age.

It has been suggested that the Public Works and Health

Departments might do good service together in promoting the health and comfort of the poor in a very simple way, now that New York, thanks to the new aqueduct, has at last an abundance of Croton water. Apartments in tenement houses are, as a rule, provided with stationary wash-tubs, and two of these tubs are generally placed side by side. The partition between the two is immovable; but if it could be taken out, and the two wash-tubs thrown into one, the tenants would have a bath-tub at their command. The Croton water rates upon bath-tubs have been so high that the use of this great convenience has been restricted, and the insufficiency of the water supply has been alleged as the reason. That reason exists no longer, and the official who would aid the tenement house dwellers in securing bath-tubs in their rooms, would certainly deserve to be classed as a public benefactor. P. B. P.

Section of Physiology and Dietetics.

To the Editor:—By order of Chairman C. H. A. Kleinschmidt, those interested in the Section of Physiology and Dietetics are invited to present papers or essays, and send titles to the undersigned, that we may get up the programme as soon as possible.

EPHRAIM CUTTER, Sec'y.

1730 Broadway, New York.

NECROLOGY.

Increase S. Hamilton, M.D.

Dr. I. S. Hamilton, one of the pioneer physicians of Southern Michigan, died at his home in Tecumseh, July 25, aged 82½ years. He graduated from the University of N. Y. at Fairfield in 1835, and at once started for the Territory of Michigan. Being without means he walked from Detroit to Lenawee County, where he practiced medicine for over 52 years. He encountered all the hardships and privations incident to professional life in the wilderness; building the first frame house and opening the first school in his part of the county. He was a pioneer in all religious and educational enterprises of the time. His reputation was unusually large for a country practitioner. He gave much attention to the diseases of women, and in their treatment, many years ago, he originated and successfully used "massage" when it was not recognized by the profession. He was a corresponding member of The Detroit Academy of Medicine, a member of The Southern Michigan Medical Society; The Michigan State Medical Society, and The American Medical Association.

MISCELLANY.

AN ARMY MEDICAL BOARD will be in session in New York City, N. Y., during October, 1891, for the examination of candidates for appointment in the Medical Corps of the United States Army, to fill existing vacancies.

Persons desiring to present themselves for examination by the Board will make application to the Secretary

of War, before September 15, 1891, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from whence they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between 21 and 28 years of age, and a graduate from a Regular Medical College, as evidence of which, his diploma must be submitted to the Board.

Further information regarding the examinations may be obtained by addressing the Surgeon-General U. S. Army, Washington, D. C.

C. SUTHERLAND, *Surgeon-General, U. S. Army.*

THE MEDICAL PRESS ASSOCIATION will meet in St. Louis October 14, on the first day of the meeting of The Mississippi Valley Medical Association. It is desirable that every Medical Journal in this country shall have its representative present on that occasion.

MEDICO-CHIRURGICAL COLLEGE OF PHILADELPHIA.—The following changes have been made in the Faculty: Dr. G. E. Stubbs, Emeritus Prof. of Clinical Surgery. Dr. W. S. Stewart, Emeritus Prof. of Obstetrics and Clinical Diseases of Women.

Dr. H. E. Goodman, Honorary Prof. of Surgery, Clinical Surgery and Orthopædics.

Dr. J. M. Anders, Prof. of Principles and Practice of Medicine, Clinical Medicine and Hygiene.

Dr. E. E. Montgomery, Prof. of Obstetrics and Gynecology.

Dr. Ernest Laplace, Prof. of Surgery, Pathology and Clinical Surgery.

Dr. W. F. Waugh, Prof. of Clinical Medicine.

THE TREATMENT OF FISSURED NIPPLE.—Dr. Barton Hirst, of Philadelphia, in the *University Medical Magazine* for March, advises the use of an application of equal weights of castor oil and subnitrate of bismuth in the treatment of fissure of the nipple. The nipple and adjacent parts should be thoroughly washed and disinfected before applying the ointment. One of the advantages of this application is that it need not be removed if it becomes expedient for the child to nurse at that breast. The ointment makes a smooth and flexible coating, which not only serves as an efficient protective, but tends to reduce the pain and reflex irritation. For the mammary engorgement and pain that so frequently occur when the nipple becomes fissured, he advises the employment of lead water with laudanum, in addition to the ordinary sling-compress. The entire breast should be covered with a cloth wet with the lotion, and the applications should be repeated at short intervals. This line of treatment ordinarily prevents the formation of abscess. It is best to allow the unaffected breast alone to be nursed, and the milk from the affected side can be drawn off with the breast pump. If it is imperative that the infant shall nurse at the fissured nipple, a glass shield with a rubber tip may be used.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from July 25, 1891, to July 31, 1891.

Asst. Surgeon Junius L. Powell, granted leave of absence for two months, on surgeon's certificate of disability, with authority for his admission to Army and Navy General Hospital, Hot Springs, Ark.

Surgeon Curtis E. Munn, U. S. A., is granted leave of absence for twenty days, to commence on or about August 5, 1891.

ORIGINAL ARTICLES.

DEATHS FROM CHLOROFORM AND ETHER SINCE THE HYDERABAD COMMISSION. WITH CONCLU- SIONS.

*Read in the Section of Surgery and Anatomy, at the Forty-second
Annual Meeting of the American Medical Association,
held at Washington, D. C., May 5-8, 1891.*

BY LAURENCE TURNBULL, M.D., P.H.G.,
OF PHILADELPHIA, PA.

We live in an age of wonderful progress ; in nothing is this better proven than in the multiplication of new and valuable books. The works of even one year becoming almost obsolete, new editions and new works taking their place. This is also the case with original experiments and investigations, crowding out the old. Nothing is lacking in either men or money. One of the most munificent works of this kind has recently been undertaken in even far-off India ; the sum of five thousand dollars having been spent by the Nizam of Hyderabad in experiments on anæsthetics alone. This large sum was given, owing to the devoted efforts of Surgeon-Major Lawrie, of the Army of India, who is a great admirer and believer in the opinions held by the late Professors Syme and Simpson, of the Edinburgh School, in regard to chloroform.

There were two Commissions, one held in 1888, in which 141 dogs were killed by chloroform inhalation, and the symptoms and results of careful post-mortems were made. The chief conclusions which were arrived at, were, "that it is impossible for chloroform vapor to kill dogs by acting primarily on the heart, and this holds good, no matter in what doses, or in what manner the poisoning is induced." These conclusions having been received with doubt by many physiologists, and more especially by the editors of the *London Lancet*, led to the Second Commission, and Dr. Lauder Brunton, a well known author and physiologist, was added to the Commission. The conclusions of the Second Commission were published January 19, 1890. About six hundred animals, chiefly dogs, were employed in the investigations.

"The experiments of the committee were de-

signed to show the effect upon the blood-pressure, heart, and respiration of the inhalation of chloroform, ether, and the A. C. E. mixture, administered in various ways and under varying conditions. The objects of the Commission were five in number :

1. To test the suitability and safety of chloroform as an anæsthetic. The experiments with ether and the A. C. E. mixture were instituted principally for the sake of comparison with chloroform on certain points, and it is not pretended that they afford a complete exposition of the action of those agents on the system.

2. The effect of pushing the above-named anæsthetics (a) to a dangerous degree, and more especially until the respiration ceases ; (b) until death results.

3. The modifications in the effects of these anæsthetics which result from (a) asphyxia in varying degrees and produced by various means, (b) from the use of drugs, such as morphine, atropine, physostigmine, and others.

4. The reality or otherwise of the alleged liability during ordinary chloroform administration to the occurrence of primary or secondary syncope or stoppage of the heart, brought about either by shock or through fatty or weak heart, or by hæmorrhage, or by changes in the position of the body. To investigate these points, in the first place a large number of operations, which are reported to be especially dangerous in reference to shock, were performed in every stage of anæsthesia, and numerous experiments were also made to show the effect of direct irritation of the vagus. Secondly, a number of animals were dosed with phosphorus before they were experimented on. This caused the weakening of the heart by fatty degeneration of its fibres, but at the same time other complicated changes in the whole of the organs of the body, not met with in the condition known as fatty heart in human beings. On the other hand, there are conditions often found in the fatty heart, such as changes of the coronary vessels, which were not produced by the phosphorus.

5. The effect of the anæsthetics above mentioned upon different animals, more especially upon monkeys, as the nearest approach to human beings."

We will not occupy your valuable time in giving the conclusions of the Commission in detail, but would refer you to the *London Lancet* and other journals which published the report. We will only state, in brief, the practical conclusions arrived at as to the effects of chloroform, "That in every instance the respiration stopped before the heart," and all that was necessary for safety was to attend to that alone. Soon after the publication of the views thus expressed, several practical English chloroformists gave their opinion, founded on professional experience, that chloroform was by no means to be considered safe by simply attending to the respiration, and that the heart still played a most important part in the deaths, as may be seen from the numerous deaths from syncope given in our tables.

With this view, I have made a most careful collection of all the deaths both from chloroform and ether, from every available source, assisted by several friends. These forty-three deaths have been arranged in a tabular form, giving the name, age, history, nature of operation, anæsthesia used, amount used, apparatus employed, posture, how long under influence, whether heart or respiration stopped first, means to resuscitate, how long continued, post-mortem, cause of death, and references.

The result of examinations and analysis of the table will be found on pages following.*

The whole number of deaths from chloroform and ether are forty-three. Of this number, thirty-nine were deaths from chloroform and four from ether. In five cases, the cause of death was syncope from chloroform, and in thirteen cases the heart stopped first. In ten cases the respiration stopped first, and in four cases the heart and respiration ceased at the same time. In one case cyanosis; no pulse. In twelve of the cases it is not stated which stopped first.

The cause of death in case 37, was due to some peculiar idiosyncrasy. In No. 22, paralysis of the pneumogastric nerve, the direct effect of the chloroform, superinduced by efforts at vomiting. After a careful consideration of the report of this case, and, as there was cyanosis after vomiting, we suspected suffocation, but this cannot be confirmed, as there was no autopsy. In case 20, there was given as cause of death, "Reflex paralysis of the heart," but there was no post-mortem to confirm this statement.

There were twenty-one post-mortems, most of them very imperfect. Nos. 24, 25, 36, and 37 were full and complete, and Nos. 15, 19, 21, 28, and 34 were fairly described in this particular.

Many of the cases were very imperfect in their detail, especially those from New South Wales.

Sufficient cases are given to show the absolute importance in the method of administering chloroform, and to indicate the necessity of the most careful attention to the pulse and respiration. The only death from anæsthetics in Philadelphia, during the period stated, was one from chloroform (No. 36), while not a single death from ether in the numerous hospitals and operations—indeed we may say in the thousands of operations.

The thirty-nine deaths from chloroform added to the 375, collected by us from our work for Dr. H. C. Wood (contained in his address before the International Medical Congress, at Berlin), make, up to the present time, 414 cases—the actual number being far greater of cases never reported.

The exceeding small number of deaths from ether, demonstrates its great safety; still, that it will and does kill (and we notice that the feeble, and persons suffering from malignant disease are more apt to be its victims, see Nos. 10, 11, and 18), we would advise its use as an anæsthetic, and a full study and knowledge of the best modes of using it; which we judge is not the case in Europe.

It is true that "chloroform acts more rapidly than ether, is pleasanter to take, causes less congestion of blood in the veins, is much more portable and handy." The last two qualities render it preferable in certain classes of operations, *e. g.* in those on the eye, and in military or traveling establishments. On a campaign it would be impossible to find room to carry ether, or time to use it.

Again, ether cannot be used in hot climates or in close proximity to artificial light; nor is it suitable in certain conditions of the lungs, because ether is more apt to cause suffocation than chloroform, which is given with a much greater admixture of air. Against these advantages on the side of chloroform, ether has only one, which, however, is sufficient to outweigh them all; it is safer.

With regard to occasional unexplained deaths under chloroform, it must be remembered that they occur also under ether, though not so frequently, and used to occur in a similar way before the use of anæsthetics at all. Dr. Brunton also had several accidental deaths; but in every case, "the usual chloroformist was absent, and no one was attending to the chloroform"—a most significant statement. How often might the same be said (with a stress on the word "attending") in our hospital practice! The Hyderabad conclusions really imply a tremendous indictment against the administrators of chloroform—nothing less than that of causing death by carelessness. Unhappily, no one familiar with the administration of anæsthetics can doubt that there is some ground for this. How else account

*In preparing the "Table of the Deaths from Chloroform and Ether, since the Second Hyderabad Commission," we have received the assistance of Professor H. A. Hare, Dr. Joseph Leidy, Jr., and especially the kind labors of Dr. J. Melvin Lamb of the Library of the Surgeon-General's Office, U. S. A., at Washington. Every facility has also been afforded us by the lady Librarian of the College of Physicians of Philadelphia, and to all of these we return our thanks.

for the widely differing records of different administrators? Every surgeon knows that with good chloroformists he is perfectly confident and easy, with others the reverse. The last word has by no means been said upon this controversy; but if we may venture a prophecy, it is that the answer to the question "Is chloroform safe?" will eventually be, "That depends on who gives it."

We would refer to the experiments of Drs. H. C. Wood and H. A. Hare (*Medical News*, February 22, 1890), results which are positive proofs in opposition to the experiments and statements of the Commission, that chloroform may arrest the heart before arrest of respiration. In one experiment, breathing continued two minutes after the heart had ceased to act.

The Pulse During Chloroform Anæsthesia.—A case in point, in which chloroform so depressed the pulse, that ether had to be resorted to. The British Medical Committee (1890) on anæsthetics,¹ after examining the kymographic tracings taken by the Hyderabad Commission, cannot agree with the Hyderabad Commission in holding that there is no danger to the heart during the administration of chloroform. Both committees have found that death occurs by failure of respiration in the great majority of cases, and that chloroform causes a gradual fall of blood pressure, which in itself is a source of danger. Both have also observed that in addition to this gradual fall, there may be sudden and unexpected falls, with slowing of the heart; but as to the explanation of these falls, they differ. The Hyderabad Commission holds that these falls, during which life is in jeopardy, are caused by asphyxia, while the British Medical Association Committee affirm, that they are due to failure of the heart, due to a specific action of the chloroform upon the organs (from which ether is free). The general conclusion of the British Medical Association Committee is, that while recognizing the great value of the work done by the Hyderabad Commission, and more especially as aided by Dr. Lauder Brunton, they consider that the commission attach too much importance to the most common mode of death from chloroform—failure of respiration—and fail to recognize the danger to the heart that may arise in certain physiological conditions. They consider it unwise and unsafe in practice to pay no attention to the state of the circulation, and to observe respiration alone. Further they consider it unwise to convey to the public, even through the profession, the notion that there is practically no danger in the administration of chloroform."² In the *Manchester Medical Chronicle*, January 7, 1891, (page 276), Dr. Lawrie, President of the Hyderabad Chloroform Commission, makes the

following statement in answer to Alexander Wilson, and others, in their reviews of the Hyderabad Commission, published in the *Chronicle* of February 9, 1890. Wilson concludes his review as follows: "Increased knowledge has added nothing new to the direction for its (chloroform) administration." Lawrie states, "The Hyderabad Commission was appointed to confirm or disprove Syme's and Simpson's principles, that we should be guided as to the effect of chloroform entirely by the respiration. The Commission has not only proved that these principles are sound, but has also proved that the art of administering chloroform with safety consists in keeping the breathing absolutely regular throughout the inhalation. This proof is new, and has never been established before. After criticising the teachings of Wilson, he states that the Commission has shown, 1, that the lowering of the blood pressure, which chloroform and all anæsthetics cause when efficiently administered, is in itself a harmless event, if the respiration alone be attended to and taken as a guide, and if the administration be stopped when the patient is fully anæsthetised; and 2, that the sudden falls of pressure, which the Glasgow Committee asserted, are dangerous, and attributed to chloroform, are due to stimulation of the vagus, and, by slowing the circulation, are a safeguard against overdoing.

The Commission further proved that all irregularities in the fall of the blood pressure, and in the circulation under chloroform, including such an irregularity as dilatation of the heart, which occurs when chloroform is administered properly, are due to improper administration with irregular breathing and insufficient air (page 277). Again (page 278), every medical man ought to be able to give a dose of chloroform with as much precision, as certainly as a dose of morphine, or of any other poison. The practical outcome of the disastrous teachings of the Glasgow Committee, backed up by Professors Wood and MacWilliam, is, that the relief of pain by chloroform is to be handed over to the specialists, who alone are to administer it, though their own declarations and statistics show that they cannot give it with safety. Exactly in proportion as this teaching gains ground, the profession suffers loss in credit, and in pocket, and the advantages which chloroform confers are most seriously restricted and curtailed.

The extensive experiments of the Commission have left the chloroform question in the following condition:

It was not found possible to directly paralyze the heart (of dogs) by chloroform in some 600 administrations. Death from chloroform is due apparently from paralysis of the vaso-motor and respiratory centers—probably one or both of these may be affected. When death occurs, it is the result of an overdose of the drug.

Note 1.—Paralysis of pneumogastric nerve, the direct effect of the chloroform, superinduced by effort at vomiting.

Note 2.—Respiration failed gradually, at one time stopping, and commenced again after artificial respiration.

Note 3.—Anæsthesia not complete when operation commenced, and heart and respiration ceased.

The most conclusive statements and experiments are given in the paper of Dr. McWilliam in answer to the strictures and conclusions published by Dr. Lawrie.

In the *Medical Chronicle*,³ January, 1891, Surgeon-Major Lawrie, in an article on the Hyderabad Chloroform Commission, makes some comments on certain results obtained by me in a recent investigation on the action of chloroform and ether published in the *British Medical Journal*, October 11, 18, and 25, 1890.

In my paper I described the frequent occurrence of dilatation of the whole heart under the influence of anæsthetic doses of chloroform. Such dilatation was not due to changes in the pulmonary circuit, or to fall of arterial pressure.

Dr. Lawrie urges that the cardiac dilatation was due to obstruction of the circulation of the lungs, or to this along with a fall in the blood pressure. He says: "The irregularities in the tracings of the Glasgow Committee, and Professor McWilliam's recent bogie of dilatation of the heart, are due to obstruction of circulation in the lungs through interference with, or irregularity of, the respiration." And later, "Obstructed circulation in the lungs, and a rapidly falling blood pressure, are more than enough to account for the dilatation of the whole heart, which occurred in his experiments, and which he wrongly attributed to the direct action of chloroform."

Nor can this hypothesis of Surgeon-Major Lawrie's be briefly and conclusively disposed of. There is an abundance of decisive evidence avail-

able. First, as regards the alleged influence of obstruction of the circulation in the lungs, in causing dilatation of the heart. In my paper, in the *British Medical Journal*, I stated the fact that such an explanation was incompetent to explain the cardiac condition, since the whole organ was dilated in my experiments. Dilatation of the right side of the heart might conceivably (if there were no evidence to the contrary) be accounted for by the pressure of pulmonary obstruction, but dilatation of the left side (*e.g.* the left auricle) could clearly not be accounted for in the same way, since pulmonary obstruction necessarily diminishes in a large measure the flow of the blood into the left auricle, and this part becomes small and collapsed. This seemed so obvious to me, that I did not discuss the matter at any great length.

I shall now state, briefly, some facts in regard to Surgeon-Major Lawrie's hypothesis of obstructed circulation in the lungs:

1. There is no proof whatever of the occurrence of pulmonary obstruction from the administration in mammals of anæsthetic doses of chloroform, sufficiently diluted with air, as was the case in my experiments, the amount of chloroform vapor in the air never exceeding four per cent.

2. On the other hand, there is decisive proof that pulmonary obstruction was not present in my experiments. Obstruction of the circulation would necessarily cause distension of the pulmonary artery as well as, and indeed earlier than, distention of the right heart. The pulmonary

artery would become large and tense in consequence of the increased peripheral resistance to the outflow of blood from that vessel. Then the increased tension would react upon the right heart and cause distension there also. But in my experiments there was no distension of the pulmonary artery during the administration of chloroform. The vessel did not become distended; it was soft and compressible, and the tension within it was low. It is quite certain, then, that pulmonary obstruction could not have been the cause of the dilatation, even on the right side of the heart.

3. Even if pulmonary obstruction had been present—as was not the case—such obstruction could not have produced the condition which I described, or anything similar to it.

I have on various occasions purposely brought about a condition of pulmonary obstruction by mechanical means with a view to studying the features of this condition. This I did by injecting into one of the great systemic veins some particular substance, *e. g.* lycopodium powder, which would cause embolism of the pulmonary vessels and so obstruct the circulation in the lungs. When such a substance is injected into the vein, it rapidly passes through the right heart into the pulmonary vessels, speedily causing more or less extensive and sudden obstruction of the pulmonary circulation, according to the amount and suddenness of the injection.

The effects resulting from the plugging of the minute pulmonary vessels induced in this way are very noteworthy, and illustrate clearly the consequence of obstruction of the circulation of the lungs. The pulmonary artery swells up and becomes largely distended, while at the same time the vessel feels hard and tense to the touch; the

pressure within the vessel is greatly elevated. The right ventricle, and the right auricle also, partake in the condition of distension, being unable to discharge their contents in the normal fashion in face of the greatly augmented resistance in front. The lungs become pale and anæmic. Meanwhile it is important to observe that the left auricle becomes smaller and collapsed-looking, in consequence of the obstacle offered to the passage of the blood through the lungs. Strong respiratory efforts, with convulsions of the asphyxial type (accompanied by spasmodic contraction of the systemic arteries) supervene in consequence of the stoppage of the respiratory purification of the blood; the medullary centres become violently stimulated by the venous character of the blood. Death speedily follows.

It is unnecessary to enter closely into a comparison, or rather contrast, of the typical illustration of pulmonary obstruction here afforded, and the condition of cardiac dilatation which I have described as occurring under the influence of chloroform. It is obvious that obstruction of the circulation in the lungs produces changes strikingly different from those that result from the action of chloroform; and that the hypothesis of pulmonary obstruction may at once be dismissed as entirely insufficient and inapplicable, as far as explanation of the cardiac dilatation occurring under chloroform is concerned.

Seeing that it is easy to dispose of the question of pulmonary obstruction in regard to the effects of chloroform upon the heart, I shall now advert briefly to the possibility of cardiac dilatation being dependent on a rapidly falling blood pressure, as alleged by Dr. Lawrie.

This is a matter which I carefully considered

in my paper, and in regard to which I was able to state definitely that the cardiac dilatation is not due to a fall of blood pressure. This is conclusively proved by the following facts: 1. Dilatation of the heart does not by any means always run parallel to the fall of pressure which ordinarily results from the administration of chloroform. Sometimes there is a very marked fall of pressure, with little or no dilatation of the heart; while at other times, the heart begins to dilate, before the pressure begins to fall. 2. Moreover, the heart in some instances begins to dilate during the temporary rise of pressure which at times precedes the fall. 3. Further, there may be distinct dilatation of the heart without any change of pressure at all. 4. Lastly, it can easily be shown that a simple fall of pressure, equal in amount to that which ordinarily occurs under chloroform, induced by means which do not directly affect the heart—*e. g.*, section of a vaso motor nerve, hæmorrhage, etc.—does not cause dilatation of the organ as chloroform does.

It is clear, then, that the dilatation of the heart brought about by chloroform cannot be due to obstruction of the circulation in the lungs, or to a fall of systemic blood pressure; it must result from a depressing influence exerted by the anæsthetic on the organ, 1, directly; or 2, through the vagus nerves.

Finally, as this depressing influence, leading to dilatation, is readily manipulated after section of both vagi, it is obvious that chloroform must act upon the heart directly. I cannot help feeling that even a comparatively slight amount of actual observation of the features and results of a simple lowering of the blood pressure and of real pulmonary obstruction, would have prevented Surgeon-Major Lawrie from putting forward and adhering to such a hypothesis as I have here discussed—a hypothesis at once insufficient, absolutely untenable, and in conflict with large and somewhat elementary facts in the physiology of the circulation.

RESTORATION AFTER CHLOROFORM ASPHYXIA.

There is no doubt that in India deaths do occur (see case No. 43) from the administration of chloroform, yet we know from the facts stated in our work, that the climate of that region, like that of our Southern States, is favorable to its use as an anæsthetic. Recently there has come to our notice, while in search for facts on the subject of prevention of deaths from chloroform, the following cases and opinions of practical surgeons, which we consider worthy of your most serious attention.

Two cases of chloroform asphyxia were reported by Surgeon-Major Bartholomew and Civil Surgeon Ahmedabad. *a.* A patient aged 31, thin and emaciated, had suffered eight years from vesical calculus. He was operated on and the stone,

weighing 50 ozs., extracted, when it was observed that respiration had ceased. Ether hypodermically and the usual remedies were used without effect, and artificial respiration (Sylvester method) continued for three hours before the patient took a long breath (the heart action, though feeble, had not ceased). Six drachms of chloroform had been given.

A patient aged 18, had had 5 drachms of chloroform given prior to enucleation. After the operation the breathing was observed to have ceased, and the patient could not be roused. Artificial respiration was carried on for one hour, and on giving a galvanic shock, the patient recovered consciousness. Drs. Pechey, Phipson, Banks, Maconachie, Meyer and Collee, all of the Army of India, cited instances in their experience of prolonged chloroform asphyxia, and ultimate recovery by artificial respiration and the galvanic shock. Dr. Meyer stated, that there was a danger of inducing delirium of the heart by the prolonged use of electricity (this is the case when applied too near the heart), and thereby superadding a serious complication which might in itself prove fatal. Frequently patients did not breathe for some time after artificial respiration, because the lungs had had such a large quantity of air thrown in as to do away with the physiological reflex stimulus to the respiratory centre.

We do not in our work advise the use of hypodermics of morphine or atropine before the use of chloroform as an anæsthetic, and would call attention to this case, also, as the surgeon did not employ the galvanic shock, and did not keep up the artificial respiration long enough.

In a discussion which took place in the Paris Society of Surgery, upon a paper treating of the use of hypodermics of morphine and atropine before the inhalation of chloroform, the author of the paper, M. Regnier, was led to try this method in his practice by the recommendation of M. Dastre, who reported favorable results from its use in animals, and of M. Aubert, a surgeon, who stated that narcosis and awaking were facilitated by the injection of $\frac{1}{4}$ gr. morphine muriate and $\frac{1}{8}$ gr. atropine sulphate fifteen or twenty minutes before the operation, and that inconvenient results were observed but rarely. M. Regnier used this method with a number of patients, until, unfortunately, a fatal accident occurred.

A feeble girl, aged 16, was affected with tubercular disease of the bones of the foot, and, as the lungs presented but a few râles in the apex of one side, he decided to chisel out the cuboid bone. Half an hour before the operation he gave a hypodermic injection of $\frac{1}{12}$ gr. of morphine and $\frac{1}{256}$ gr. of atropine. Anæsthesia was easily induced, and not more than from 5 to 7 fluid drachms of chloroform were required for the

whole operation, which lasted only a few minutes. About ten minutes after the chloroform had been removed, and while the dressings were being applied, she opened her eyes without speaking, and was then carried to her ward. Three minutes later news was brought that she had ceased breathing. Upon reaching her bed he found the respirations very infrequent. They ceased suddenly as the pulse disappeared, although feeble heart-beats were still heard. The pupil then quickly dilated. Protracted artificial respiration seemed, at the end of half an hour, to excite spontaneous respiration, but this soon failed, although supplemented by ether injection and other measures. Post-mortem examination showed anæmia of the cerebral hemispheres and medulla oblongata.

Death in this case came on very slowly from chloroform intoxication: It was quite remarkable that life could be prolonged for more than twenty minutes by artificial respiration. It was claimed that the chloroform must have been eliminated slowly, and that the elimination was rendered more slow than it would otherwise have been by the influence of the morphine and atropine.

Two members of the Society reported that they had observed, in experiments on dogs, that morphine and atropine given before chloroform, produced no reflex phenomena at the beginning, but rendered much more grave such complications as appeared at the end. In some cases there was quite protracted and severe dyspnoea. In dogs thus treated, very little chloroform was needed; in men more was required. It appeared to be conceded that the method was useful in the laboratory, but not in the clinic, as the chances of intoxication were increased.

Another member who had tried the method, stated that in male patients nothing worthy of note was usually observed; while in female patients, the awaking was much more slow than with chloroform alone. He thought women were more sensitive than men to the influence of atropine. Out of five cases he had lost one patient. The operation was for nephrectomy, and lasted an hour, 15 fluid drachms of chloroform being used. After a short awakening the respiration began to fail, cyanosis appeared, and in spite of all measures, death occurred in an hour and ten minutes.

CONCLUSIONS.

1. During the protracted use of chloroform as an anæsthetic, the blood is changed in character, lowered in pressure, with weakening of the action of the heart and changes in its structure.

2. Dilatation of the heart occurs under the use of chloroform at all stages, on both sides of the heart, while the heart muscle is weakened.

3. Cardiac failure occurred before respiration

in thirteen instances out of forty-three cases of death from chloroform.

4. The depressing influence of chloroform on the heart mechanism is not exerted through the vagus nerves, and section of both vagi does not obviate the weakening and dilating influence of chloroform on the heart.

5. Too many trifling operations are performed under chloroform; its use should be reserved for those cases in which ether, nitrous oxide, or cocaine will not produce the anæsthesia desired.

6. Ether deaths, as a rule, occur in patients of a certain class, usually from obstructed respiration, and occasionally the heart will stop first, as in two of the four cases in our tables.

7. Watch both pulse and respiration, both in chloroform and ether; when the breathing becomes very rapid, danger is near.

These changes are apt to follow the first act of respiration. Chloroform vapor should not be employed over 4 per cent.

RELATIONS OF METEOROLOGICAL CONDITIONS TO THE ORIGIN AND PREVALENCE OF ACUTE DISEASES.

Report of the Standing Committee to the Section on State Medicine of the American Medical Association, May, 1891.

BY N. S. DAVIS, M.D., CHAIRMAN,
OF CHICAGO.

The work originally assigned to your Committee was commenced by its chairman in 1874,¹ and it was prosecuted with more or less activity and success until 1885, since which time it has received less attention.

Reports containing important facts and the results of original investigations were made and published in the volumes of Transactions of the Association for 1875, 1877, 1879, 1881 and 1882, and in THE JOURNAL of the Association, Vol. ii, pp. 85-169.

The leading object of the Committee has been to obtain more exact and reliable knowledge concerning the causes and circumstances that originate, or increase the prevalence of, the various forms of acute disease; by procuring and preserving continuous daily records of all appreciable conditions of the atmosphere, water and soil, and coincident record of the date of the commencement of acute diseases, in localities representing different parts of the country and various climatic conditions. For details of the plan adopted and its practical working, I must refer you to the report made to the Association in 1883, and published in THE JOURNAL, Vol. ii, pp. 85-169, 1884. That report included the results of one year of observation and record of the ozone and hydrogen peroxide in ten or twelve stations, as

¹ See Trans. Amer. Med. Association, Vol. xxv, pp. 105, 106.

indicated by uniform test papers, and in Chicago a complete record of the relative amount of free and albuminoid ammonia for the same period of time, as determined by Professor J. H. Long, of the laboratory of the Northwestern University. These records, in connection with those previously made, enable us to deduce the following propositions:

1. That the indications of the presence of ozone and hydrogen peroxide in the atmosphere vary very much at short distances, being generally increased by high winds, cold dry air, and proximity to large bodies of water, and diminished by still, warm and moist air, and still more in the interior of cities, houses, and densely populated districts.

2. That an appreciable amount of both free and albuminoid ammonia is almost always present in the atmosphere, especially in cities and densely populated districts of country. The albuminoid is much more abundant than the free ammonia, and being chiefly derived from putrefactive changes in animal matter, its relative prevalence is greatest during the autumn and early winter months, and least during the spring and early summer, when it is most actively consumed by growing vegetation.

3. The observations of Prof. Long and others show that putrefactive processes in the presence of moisture favor the production of free ammonia, while with greater dryness, more albuminoid ammonia is liberated, and that both are capable of being carried by atmospheric currents several miles from their source. His experiments, as detailed in the report of 1884, also show that the free and albuminoid ammonia are directly acted upon by the ozone, and their identity destroyed by entering into new combinations or being resolved into ultimate elements.

If these propositions are correct, they point directly to the important fact that whenever we have, coincidentally, an abundance of decomposable animal matter on the earth's surface, a favorable temperature, slow atmospheric currents, a minimum of moisture, and little active vegetable growth, albuminoid ammonia will appear most abundant in the atmosphere; sufficiently so, it would seem, to either become the pabulum for the rapid growth of pathogenic germs, or for the evolution of toxalbumens or ptomaines, and thus aid in explaining the rapidity of development and spread of some important epidemics.

On the other hand, when we have coincidentally, either dry cold air or rapid vegetable growth with rapid atmospheric currents, and frequent fresh falling water, we have increased indications of the presence of the active oxidizers, ozone and hydrogen peroxide, with the minimum of albuminoid ammonia in the atmosphere. The influence of these combinations of atmospheric elements on the prevalence of both endemic and

epidemic diseases, is pretty clearly shown by the recorded observations made in Chicago during the last ten years, particularly in reference to typhoid fever, pneumonia, and epidemic influenza or la grippe.

In speaking of atmospheric and climatic conditions at Chicago, it should be borne in mind that the city is built on nearly level ground, skirted for many miles to the east and northeast by Lake Michigan, and to the west and southwest by a still broader expanse of nearly level, rich prairie country, while the most prevalent winds are from the southwest and northeast. The winter of 1880-81 was characterized by at least the average degree of coldness and other ordinary atmospheric conditions, but was followed late in March, 1881, by an extraordinary fall of snow over a wide district of country. Melting rapidly, it caused unusual floods and thorough saturation of soil during the month of April. But for three months following May 1 there was not enough rainfall to wet the dust in the streets, and only an ordinary average during the months of August and September, while the prevailing winds were from the southwest, and unusually light or slow. This early complete saturation of the soil, followed by protracted dryness, with average summer heat and comparatively slight atmospheric currents, strongly favored the formation of an unusually large amount of albuminoid ammonia, with only occasional traces of ozone. The records of disease and mortality show that early in June attacks of typhoid fever began to be more frequent, and the number increased rapidly through July and August, culminating in September, and then declining to the ordinary average through October and November. During the eight months from May 1 to December 31, 1881, the whole number of deaths from typhoid fever, as reported to the city Health Office, was 527; while the total number reported for the corresponding months of 1880 was 143, and for the same in 1882 was only 235. As the extraordinary prevalence of typhoid fever in 1881 diminished to nearly the average of other years in November and December, attacks of pneumonia began to increase, and culminated in a decided excess above the average in January, 1882, when 122 deaths were recorded from that disease, whereas only 48 had been recorded during the corresponding month of the preceding year. But the most important fluctuations in the prevalence of certain diseases, and coincident extraordinary atmospheric conditions, have been observed during the years 1890 and 1891.

At the annual meeting of the American Medical Association, May, 1890, I had the pleasure of reading a brief paper on the meteorological and other local conditions coincident with the prevalence of epidemic influenza in Chicago during the preceding winter. But as the figures regarding

the prevalence of diseases given in that, were limited to the older twenty-four wards, and included only the two months prior to the appearance of the epidemic and two months after its subsidence, I have taken the liberty of extending my observations regarding the further prevalence of that disease in the same city, and its relations to the prevalence of other diseases of importance. The statistics given in this paper relate to the entire city, with a population, as by the census of 1890, of 1,100,000. The diseases considered will be designated as pneumonia, other acute affections of the respiratory organs, influenza or la grippe, typhoid fever, acute diarrhoeal diseases and sunstroke. The acute diarrhoeal diseases will include cholera infantum, cholera morbus, diarrhoea and dysentery. The following tables have been carefully compiled from the books of the Registrar of Vital Statistics in the Health Office of Chicago, and extend over the entire years 1889, 1890, and the first quarter of 1891. Of course they refer only to deaths, and afford a basis for only a proximate estimate of the number of attacks of each disease.

MORTALITY FOR YEAR 1889.

Cause of Death.	Jan.	Feb.	Mar.	April.	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.	Total

													6484

foregoing tables, as shown for 1889, is very nearly the average ratio of mortality from the same diseases for a series of years. If there is any deviation, it is in a slight excess of mortality from diarrhoeal diseases during the early waves of high temperature in July, accompanied by a few sunstrokes. Taking that year as the standard of average mortality, not only for the year but also for the several seasons of the year, we are enabled to see the marked deviations from that in the table for 1890 and the first quarter of 1891, both as regards the occurrence of the epidemic influenza and its apparent influence on the mortality from other diseases. Thus, while the total mortality in 1889 from pneumonia and other acute diseases of the respiratory organs was 2,106, only one-third of which occurred during the first quarter, *i. e.*, January, February and March, and only one death from the epidemic influenza, which occurred the last week of the year, the total mortality from pneumonia and other acute diseases of the respiratory organs in 1890 was 3,486, more than half of which took place during the first quarter, and for those months was double the mortality from the same diseases the preceding year. Coincidentally, the influenza epidemic that had just shown itself the last week of December, 1889, rapidly culminated in January, 1890, and almost as rapidly declined through February and March, leaving a recognized direct mortality of only 111. The reappearance of this epidemic influenza during the first quarter of 1891, at first mildly, occasioning only four deaths in January and six in February, but suddenly culminating with 155 in March, was accompanied by the same extraordinary mortality from acute diseases of the respiratory organs as in 1890.

Thus the table for 1891 shows the mortality from pneumonia in January 280, February 233, and in March 722, while that from other acute diseases of the respiratory organs was for January 176, February 172, and March 344, making the total mortality from these diseases during the first quarter of 1891, 1,927—or 149 more than the unusual mortality of the same month of 1890, and 1,200 more than in 1889, representing the ordinary average. The same influenza epidemic influence was plainly seen, though less exaggerated, on the mortality from typhoid fever and diarrhoeal diseases. Thus, during the first quarter of 1889, the mortality from typhoid fever was only 66, while for 1890 it was 292, and for the same months in 1891 it was 199. And from acute diarrhoeal diseases during the first quarter of 1889 the mortality was 29, for the same period of 1890, 151, and for 1891, 114. After making a fair allowance for increase of population during the past two years and three months, the foregoing figures show that the same etiological conditions that gave rise to the epidemic influenza in the city of Chicago, caused at the same time the

Mortality for 1st Quarter 1891.				Total for 1st Quar. '89.	Total for 1st Quar. '90.	Total for 1st Quar. '91.
Cause of Death.	Jan.	Feb.	Mar.			
Pneumonia	280	233	722	384	1096	1235
Other resp. affections	176	172	344	343	682	692
Epidemic influenza	4	6	155		108	165
Typhoid fever	67	61	71	66	292	199
Acute diarrhoeal diseases	28	42	71	29	151	141
				822	2329	2432

The mortality from the diseases named in the

mortality from pneumonia and other acute diseases of the respiratory organs to be more than doubled; from typhoid fever to be trebled; and from diarrhœal diseases to be increased five-fold.

Etiological Conditions.—In considering the etiological conditions preceding, accompanying, and following the epidemic of the first quarter of 1890, in the paper I read to this Section at the last annual meeting, it was shown that during the time of the epidemic, the water supplied to the inhabitants contained an unsafe amount of free and albuminoid ammonia and of microorganisms. It was also shown that during the month preceding the outbreak of the epidemic, the mean atmospheric temperature was 9° F. above that of the same month of the preceding healthy year, and that of the month during which it reached its climax, the mean temperature was 2.4° F. above that of the same month of the preceding year. It was further shown that during the epidemic and for three months preceding, the atmospheric currents had been light and from the southwest.

An examination of the meteorological conditions as shown by the records of the Signal Service Station in Chicago, develops the fact that, for three months prior to the reappearance of the epidemic in 1891, the prevailing winds were from the southwest, the mean temperature above the average of healthy seasons, with an unusually light precipitation, either in rain or snow, until after the climax of the epidemic influenza had been reached, and evidences of impurities in the water supply remained the same as the preceding year. When the epidemic had reached its climax the prevailing wind changed to the northeast, and an increased precipitation, chiefly in the form of light snow, followed. But on the evening of the 30th of March a copious rainfall occurred, accompanied by thunder and lightning, which was followed by a rapid decline of the epidemic and its associated diseases through the month of April.

It will be seen by our tables, that the epidemic influence that culminated in January, 1890, did not reach its climax until in March, 1891; and still the preceding and accompanying conditions of the atmosphere and water, the two elements common to our whole population, were nearly the same in both seasons. What influence, if any, the extraordinary waves of heat in June and July, 1890, may have had in lessening the vital resistance of the people, and thereby increasing the mortality from the influenza, pneumonia and acute respiratory affections that followed several months later, can only be a subject of conjecture. That the varying degrees of atmospheric heat as characterizing different seasons of the year, and different years, exert a very important influence on the physiological and pathological processes taking place in the living human body, there can be no reasonable doubt. That the influence of this agent is much modified by the coincident

degrees of aqueous vapor or atmospheric moisture, is equally certain. And, as already stated in this and a preceding paper, the varying quantities of organic products in the forms of free and albuminoid ammonia pervading the atmosphere, and their antagonistic elements, ozone and hydrogen peroxide, constitute the additional elements to which we must turn our attention in searching for the active etiological factors in such widespread and rapidly developed epidemics as influenza and dengue. The severe and protracted depressing effect of the essential cause or causes of the recent influenza epidemics, on the functions of the cardiac, vaso motor and ganglionic systems of nerves, coincident with excessive irritant action on the respiratory and digestive organs, is very analogous to the action of some of the ptomaines or toxalbumens. And it is difficult to find any other atmospheric elements than the albuminoid, that could be capable of either conversion directly into toxalbumens, or of becoming pabulum for the rapid propagation of pathogenic microbes.

HYGIENE IN THE RURAL DISTRICTS.

Read in the Section of State Medicine, at the Forty-second Annual Meeting of the American Medical Association, at Washington, D. C., May, 1891.

BY GEO. W. JENKINS, M.D.,
OF KILLEBURN CITY, WIS.

To be able to successfully combat all the diseases which flesh is heir to, "is a consummation devoutly to be wished;" but greater is it to be able to point out the hidden and lurking causes of disease, and thereby prevent the ravages it entails upon the human family—often widespread in its effects, and equally disastrous in its results.

Ever since the Lord made "man and breathed into his nostrils the breath of life, and man became a living soul," disease and death have surrounded him at every turn, and it is a lamentable fact that man, left to himself without the direction of superior intelligence, would fall into habits of neglect of necessary cleanliness, thereby bringing disease upon himself and the community in which he resides. So we read in Holy Writ that when the Lord took the children of Israel unto Himself as His chosen people, He gave them directions which would conduce to their continuance as a nation, and their health as individuals, and was careful to show them how to observe the great laws of health. One in particular in Deuteronomy 23: 12, 13, in regard to the disposition of all fecal matter—that it should be carried without the camp and properly disposed of in the earth. Moses was one of the first hygienists on record; and much better would it have been for the human family to-day if his commands had been followed to the letter.

Having had a large experience in the practice

of my profession in the rural districts, I have been impressed with the fact that the people that I have visited have been in a most lamentable state of ignorance of the fundamental principles of right living and hygienic conditions of their surroundings.

One great evil that constantly confronts you in the rural districts is the unwholesome water supply. Too often the water in wells is contaminated by surface water and drainage from the house and barn yards. The well is dug near the kitchen door to be of easy access to the family, and in close proximity to the woodpile, and year after year the well receives the wash water and slops from the kitchen, after first filtering through the chips and *debris* that lie about in the back yard. At first the earth serves as a filter for all impurities which the water contains, before it reaches the well. But after a time the earth becomes so charged with filth by constant filtration that it ceases to dispose of its impurities, and the waste from the kitchen reaches the water in the well in nearly the same condition it left the kitchen maid's hands from the washtub or slop basin.

A few cases to the point will illustrate more fully the truth of the above assertions. They are from a report of cases that I presented to the State Board of Health of Wisconsin.

A family of father, mother and five children, were all more or less sick with a fever induced, as I fully believed, by drinking water which was very much contaminated by drainage from the barn yard. The well was situated between the house and barn, with a gentle slope towards the well. The yard was very foul from the accumulation of the rubbish of years, and the water in the well became impregnated with the filth from this source, until it looked, tasted, and smelt badly. I ascertained from the family that when they moved upon the place the frost was in the ground, and the water, to all appearances, was pure and good. When the frost came out the water began to look and taste badly. Of this water all the family used until I was called to see the mother and daughter who were suffering with a malignant form of diphtheria, attended with great depression of all the vital powers and bloody passages from the bowels. I explained to them the probable cause of their sickness and forbade the further use of the water. They soon began to improve and made a good recovery, after using good water from another source. They continued to use the good water for a time, and then they returned to the use of the water in the contaminated well. The mother very soon came down with exactly the same symptoms as before. The family soon left this farm, and a German who owned it, having a family of eight children, moved upon it. He declared that the water was good and pure, and

that the doctor did not know anything about it. After using the water for a short time, one of the children came down with diphtheria, croupal form, and died in less than a week. After this every member of the family was sick of the same disease, and five of them died in less than ten days from the date of the first attack—nor was there any other cases of diphtheria in that section of the country where it proved as fatal as to this family. Is it reasonable to suppose that the cause of that sickness lay in any other direction than that filthy well? I think not.

Again, during the summer of 1881, I noticed that all the cases of typhoid fever which occurred in a certain village, were in families who obtained their water supply from one particular well. Its water was cold and looked pure. This well stood in the centre of a little square, and in the summer months, cattle and other animals were allowed to stand around its curbing fighting insects and stamping the ground, until a hole was made sufficiently large to catch all the water that was wasted during the drawing of it by the several families. In a short time this collected water in the hole was reeking with filth from the animals, and soaked through the earth into the well. I insisted that the typhoid fever originated from the water in that well, but could not make its patrons believe it contained any impurities, until I proved it to them by actual demonstration. I then ordered the ground dug up around the well down to the rock. The well from the rock to the surface of the earth contained tubing about six inches in diameter. This tubing was firmly fixed, by filling in around it cement and stone to the surface of the earth, thus effectually cutting off all surface drainage. After having the well thoroughly cleaned no more typhoid fever originated from that well, nor has there any cases occurred in that section up to the present date. Many farmers allow their cattle in the same way about their wells, with no thought of the possibility of such results.

During the past year I was called early in December to attend a case of diphtheria, in a section of country where there had been no exposure, and found on looking for the cause that the family had been in the habit of protecting their potatoes in the cellar from the frost by covering them four or five inches deep with forest leaves. On further inquiry I ascertained that these same leaves had been left in the cellar for several years, and as there was no window or outside door, the cellar could not be ventilated. The floor above the cellar was old and poor, and the emanations from the decaying leaves could be distinctly smelled. I ordered the leaves to be removed immediately, door and windows made that the cellar might be thoroughly ventilated, and chloride of lime freely used. That made an end of diphtheria in that family.

How often is it the case when the doctor enters the cellar to ascertain the cause of sickness in any given case, that he finds it poorly ventilated, containing decaying vegetables and decomposing matter of various kinds—and in this same cellar the milk is kept from which their butter is made. As milk forms so large a part of the farmers' diet it should be pure, but most farmers never think that milk can become contaminated by being kept in an atmosphere that is full of the germs of decaying substances.

The truth of the matter is this, that notwithstanding lecture upon lecture, line upon line, and precept upon precept, is given to those whom it is calculated to benefit, little good will result therefrom, unless it is given in a way commensurate to their degree of understanding and ability to receive it.

If the people living in the rural districts of our country could be made to understand the great importance of being enlightened upon this important subject, many lives might be saved and much sickness prevented, but so far as I know, no one has ever suggested any plan by which this great branch of their education might become popular and highly instructive to them. I propose to offer a few suggestions by which that object may be obtained.

My idea to gain that desired end, is, that the physicians of two or more adjoining townships should form themselves into a Hygiene society, to meet at stated times at some farmers' house, and then and there show to all that attend those meetings, the dangers that lie hidden and unsuspected about them.

Let any one member of the Hygiene society be required to report upon some subject connected therewith at any one meeting, which may be fixed by previous announcement, and report fully upon that subject, by the use of tests and other demonstrations as the subject demands, to make it intelligible and instructive to the people.

Of course this will require labor and time of the members composing the Board, but if they can prevent disease, and save life by so doing, they will be richly repaid for all their efforts—life and health are of more value than money.

It is the every day duties that we are called upon to attend to—the little details, and to point out again and again a lurking danger to health and life; it is this faithfulness in little things that accomplishes so much that is lasting and beneficial. Say that these duties are irksome—granted. What duties of the physician are not so, from the time that he begins his professional career until it ends? What is his reward?

We receive it every day in the consciousness of having been the means of preventing disease as well as saving the lives of many; and He whose eyes never slumber will surely reward us according to the motives that have prompted us to perform them.

THE BENEFICENCE OF DISEASE.

Read in the Section of State Medicine, at the Forty-second Annual Meeting of the American Medical Association, Washington, D. C., May 5, 1891.

BY A. N. BELL, A.M., M.D.,
OF BROOKLYN, N. Y.

The first thought which this title suggests to the unreflective mind is, that it is in conflict with the almost universally popular belief that disease is an independent, active principle or entity, the result of sin—a penalty for the transgression of some physiological or sanitary law—which is identified with the punishment of our first parents for partaking of the forbidden fruit; a belief which, logically considered, without any conception of organic structure, would imply that man, as originally constituted, was intended to occupy this world forever.

That disease was unknown in the world before the fall of Adam, is only equally true with the statement that so was all knowledge of the concerns of mankind unknown.

It is not my purpose to analyze the sacred record with regard to such special manifestations and miracles as appear to have been adapted by the Creator to the comprehension of man in his primitive state, or to call in question their design; but to consider disease as an essential condition of life, instituted for a beneficent purpose.

I have so long entertained this belief and have had such frequent opportunities of testing its practical utility, that, to my mind, it now amounts to a thorough conviction.

For illustration: About thirty-five years ago I was called to a very sick child, about eight years old, the daughter of a learned, but exceedingly sensitive clergyman. I found him in the room with the child, walking the floor and wringing his hands, and otherwise giving vent to his feelings by prayer; with frequent appeals to God to know why his dear child should be so stricken. "Oh, my God," he cried, "for what is this affliction sent—what has my darling child done that she should be called upon to suffer," and by various similar expressions greatly disturbing to the patient and agonizing to himself.

I, of course, led him from the room and remonstrated with him, and had to repeat the process several times during the few days next following; but finally succeeded in excluding him altogether, until the child had well nigh recovered and he had become composed.

Some two or three months afterward, the Reverend Father, who, I had learned, was the editor of a church magazine, called upon me and requested me to be kind enough to write out in substance what he had learned from me of the nature of disease, and allow him to publish it. I made a conditional promise, and after a few weeks, I wrote out enough to make half a dozen printed pages, and without caption or signature,

I sent it with a note: "Here is your baby, name it to suit yourself."

It appeared in his next issue under the title of "The Goodness of God Manifest in Disease."

This was in 1857. Three years subsequently I rewrote the article and made it the concluding chapter of a little book called "Knowledge of Living Things," published by Bailliere Brothers, New York, 1860.

What follows, comprises the substance of those articles, in conjunction with more knowledge of the structure of the human organism and continued reflection upon the subject.

Every organized being and every organ and tissue of every such being, even the hairs and nails, and the most minute nerves, after they are lost to view under the most powerful microscope, are now known to be composed and maintained by living cells. Each one of the cells thus incorporated is possessed of an individual life of its own, has a period of development and maturity, possesses the property of reproduction, and dies. Life presents itself in the organism as the sum of these vital unities. It is maintained by the circulation of the blood, which is also for the most part composed of living cells; and the processes of organization and function are sustained, or otherwise, according to the conditions of the blood supply and of the organ or organism to which it is distributed. So that all irregular actions, disturbances and pains which follow, are just as much in accordance with the laws which govern the existence of a single cell, as if the cell relied on its own independent action. And all the changes that take place, whether favorable or unfavorable to the continuance of life, are based upon the same fundamental laws.

The cells exist before the being which they organize, and survive it after the play of its functions has been arrested, inasmuch that the life of the organism, throughout, is the resultant of the life of the cells which constitute it; their individual existence being co-ordinated to subserve a perfectly definite object. When this co-ordination is interfered with, the result is disease. The favorable or unfavorable influences determine whether the already existing parts or cells persist, increase or diminish; whether the conditions necessary to the varied play of the organic functions remain, or whether the machinery of life is arrested by the change or cessation of these conditions.

The organism, like the cells of which it is constituted and by which it is maintained, has a period of development and growth; a period of middle life, in which the functions strive to maintain an unaltered mass; and an epoch of decrease or decline, which is concluded by natural death. It is only in accordance with these conditions that life is embodied.

The world was not made for man alone. His

life is linked with the plants and animals which co-exist with him, and these are the issue of long anticipations and preparations.

Not only the comfort, health and degree of civilization, but the very existence of mankind in any given locality, depends upon the state of the earth, the atmosphere of the earth, the climate of the earth, and the productions of the earth. He is placed in a system where all the changes produced in other objects occur according to a relation existing among the substances changed, and his own organization participates in all these things that surround him. He has been endowed with a degree of intelligence equal to the necessity of determining the relation of these things to his health and life, and what he ought to do for himself is as abundantly indicated by the knowledge of his organization and powers, as the uses of any machine is understood by an acquaintance with its construction.

The nature of the human organism is such that a most intricate connection is established between the organic functions, and this connection has a constant relation to the necessity of harmonizing the functions and keeping them in sympathy with each other.

The constant physical and chemical changes which accompany life depend upon the various reciprocities which are produced by the work of the different parts of the body: The assimilation of what is received, the elimination of that which is useless, and the restoration and maintenance of the organs by which these operations are effected.

We need no reasoning to convince us that an organism so curious and so wonderfully perfect in all its parts as the human body, was designed to continue as long as the material composing it and the conditions to which it is exposed will admit of, and that upon us devolves the duty of giving it that continuance.

The preservation of health is an incumbent duty. We must preserve it in its most perfect state, that in which the powers of the constitution can be most effectually exerted. All the health and strength of which we are capable were intended for use; and any unfitness for the functions of life is a partial death, by a weakening of the compensating powers of the system. The life and activity of every part is merged into such a perfect organism, that all the organs composing it are united together in a bond of mutual dependence, and the complete performance of the entire series of actions, is necessary for the healthy maintenance of any one action. All the functions are so completely bound up in each other, that none of them can be suspended without seriously disturbing or causing the cessation of all the rest. Hence if any one organ is diseased, all the other organs are embarrassed.

We are all so placed that there are very few of

the objects surrounding us which may not be serviceable or hurtful; nor is that service to be obtained or injury avoided otherwise than by an acquaintance with things external, and their relations to our existence. The more exact our knowledge of this kind is, the more we lessen the calamities and add to the comforts of life.

Our knowledge of external things wholly depends upon our sense-perceptions. To our senses we trust directly, and by their cultivation we become acquainted with the relation of external things to health, and gain the power of increasing and varying the facts upon which we rely for guidance.

When the body is in full health and strength, the mind is so far assisted thereby that it can bear a closer and longer application. Apprehension is readier, imagination livelier, the compass of thought is more capable of enlargement, perceptions can be more quickly examined and more exactly compared, and a truer judgment can be formed. We can in all things have a clearer understanding of our relation to external things, of that which is best for us and of what is most for our interest, and thence determine our actions more readily, and persist therein with greater resolution and steadiness.

It is in this way that the soundness of the body is serviceable to the mind—each needs, each helps the other.

But the lifetime of man is perfectly consistent with the temporary existence of the cells of which his body is constituted and his relation to the conditions which surround him. Under the most favorable conditions, parts of his frame that are concerned in development unceasingly accumulate the necessary particles by a process as beautiful and systematic as it is mysterious and sublime; until, ultimately, the growth peculiar to the species and the individual is attained.

At this point the preponderance which before existed in the action of the exhalants over the absorbents, ceases; and all is equality. Ere long his exhalants fall off in their wonted activity; the fluids decrease in quantity; the solids become more rigid; and all those changes supervene which characterize the decline of life.

But death may occur at any period of life, a few only ceasing to live by the effects of age alone. The duration of life varies according to numerous conditions and circumstances: The original constitution of the individual, the habits and occupations of life, locality, and various other causes, some of which, accidental or otherwise, are inappreciable before their fatal effects are encountered.

Latitude, elevation, nature of the soil, degree of cultivation, relative position in regard to mountains, forests, rivers, etc., and general aspect of the neighborhood, all modify the con-

dition of man and prove his adaptability by such effects as serve to make him understand his relations to what is around him.

Man's relation to these things are known by their effects. And with the faculty of reason for his guide in the prosecution of his purpose, he continually risks the consequences of his free agency by fortifying himself against recognized conditions inimical to his health and life, or by boldly setting them at defiance in the irregularities of his conduct.

Disease in all its aspects is no less constant than the physical phenomena of the universe. The more attentively it is studied from the earliest records of it, to the present time, the more evident it appears that not a single one of the many diseases described in ancient or modern times has wholly disappeared, or that a single new one has been discovered. The same and all exist to day, as ever have existed, and with equal liability to assert themselves under the same conditions as their want at any period in their history.

The Divine institution of disease in relation to man's free agency and the qualities of natural phenomena suited to the whole organic world, requires that there should be more or less uncertainty and irregularity in its action. Diversity and dissimilarity are everywhere manifest, and not less so in disease and its results than in the classes, orders, genera and species of the animals and plants; individuals of the same species are not unfrequently very dissimilar.

Disease forms no exception to the Divine arrangement of natural phenomena. The beginning and end of human life are only steps in an eternal existence. Death is the completion of life, but if disease had no other purpose nor end than death, it would be an anomaly in the works of the Creator, as involving an arrangement of vitality without salutary tendencies. Like our own handiwork, which has in itself no provision for repair, we should wear out; labor and sorrow would be the end of all our days; life would be a burden, health beyond hope, and eternity a new creation.

The gratification which the reasoning faculties constantly seek, even if it involve a sacrifice of individual health, discloses truths of universal application. And as man tastes of the delights of intellectual action and gives way to the impulses of his nature to pursue them, he will see in disease a providential mercy to encourage his willing submission to it and to mitigate its severity. As its pains are but temporary, he can find strength to bear them patiently, if not to welcome them in the thought of the enduring good which they are intended to work within him.

The uncertainty of the issue in any disease, however slight in the beginning, is evidence of its merciful object. Were it otherwise, were our

bodies so constituted as never to be sick but unto death, how appalling and hopeless would be the condition of man—hardened in sin, by the deliberate postponement of immortal concerns on account of the certainty of time! But the uncertain duration of, and occasional recovery from, even the most fatal diseases, guards and secures their fitness for the common purpose, and prevents them from being any exception to the Divine arrangement.

But let us go further and suppose disease to be of one kind only, and always fatal at a particular period. Then the case would be much aggravated. A deathbed repentance would be the universal reliance, for while health continued there would be no concern for a future state. Feeling sure of time for the necessary preparation, convenience and necessity would take the place of duty, and the deceptions of weakness and bewilderment, instead of strength and clear perception in the full enjoyment of health and faculties, would determine the chances of eternity.

On the other hand, people sometimes die without the intervention of disease—are suddenly cut off in the full possession of health. But such deaths are rare and exceptions to the general rule. And how would it be if they were the rule instead of the exception? How indescribably dreadful would be the fear of certain sudden death! The whole of life would consist in the dread of impending danger; pleasure would be unexperienced and unknown, and civilization among the things that are not.

Indeed, it is only by the present arrangement of disease that its Divine origin can be appreciated and its beneficence discerned. In any other way it would have no analogy to the diversity everywhere manifest in natural phenomena, nor would it serve the merciful purpose for which it was ordained.

Disease was not instituted simply as the road to death, or it would have been uniform and certain in its course. True happiness consists in the influence of religion, to which the whole of life should be devoted.

That fulness of communion which actuates the most kindly emotions, induces peace, inspires love and waits for heaven, is more or less the fruit of disease. It brings out and nourishes all the finest feelings of human nature. When strength is laid low and man is made to see and feel his dependence upon his fellowman, who that has watched and studied the motions of the faithful physician and seen the sympathy of his full heart overflow, lest through too much confidence in human aid the purpose of God may not be fully accomplished; who has seen this and not felt the benefit of the sick room? Or, again, when the surgeon has to take the responsibility of hazarding the most intense suffering with the least bare hope of relief from impending death; with

what sympathy, what self-denying devotion, the wife, the mother, the sister, the friend, aye, the enemy even, and the most abandoned of mankind, all find their feelings softened under such circumstances. But again: when disease appears in its most appalling aspect, and the heart of the Nation is stirred by the advance of a fatal epidemic on a neglectful community, to keep itself fortified against such an event, but instead, is beset round-about with the most favorable conditions for the reception and propagation of such a disease, and the life of thousands, it may be, is made to depend upon the fortitude of the practical sanitarian who is called upon to defend such a community, until it can be aroused from its sleeping indifference and made to bestir itself by the use of its reason; who that has witnessed such scenes is not ready to confess that it is in mercy and not wrath that God has sent disease into the world?

All conflict with this conclusion is removed by our Lord's blessed answer to the question, "Master, who did sin, this man or his parents, that he was born blind?"

"Neither hath this man sinned nor his parents, but that the works of God should be made manifest in him."

The apparent punishment of Azariah with leprosy for profanity, and of Gehazi for covetousness and falsehood, was in reality a correction in mercy. And in like manner were the punishments of the Israelites.

Disease is nowhere manifest as mere punishment, but as a correction in mercy for the salvation of the soul. Even when it is brought about by our own misconduct, it is consonant with this view, because we are admonished by it to be ready for death.

We are corrected against the imprudence committed for future improvement in *ourselves*, not punished that others may profit by our example, which is the true design of punishment. Moreover, as a general thing, there is no connection between acts performed and disease. Indeed, if this were the case, we should find that the righteous and the wicked could be designated by their relative degree of health, and we should be constantly led to inquire, "Who did sin, this man or his parents?"

It is conclusive that no manner of life can be alleged in justification of disease. From infancy to old age, the innocent and the guilty are alike subject to its uncertainties.

The inherent aversion of man to live for the future, needs a constant monitor.

There is no condition in which we are in so much danger of forgetting that an eternity awaits us, as when we are in the uniform enjoyment of health. The purpose of disease may indeed be disregarded, unheeded; in which case the visitation will be unprofitable, as it was to the Philistines, but its purpose is not on this account al-

tered. A thorough conviction of God's love and merciful providence in all His dispensations is the only adequate proof of a submissive spirit. And the benefit of disease is to be obtained, not by endeavoring to discover why it has been inflicted, but by meek submission to the Divine will.

It is thus that the Creator, having designed man for a higher sphere, has not only given him the capacity of knowledge and virtue, but has instituted disease as a sentinel on the threshold of his future existence.

TUBERCULOSIS AND LEPROSY IN JAPAN. A STUDY IN ETHNOLOGICAL PATHOLOGY.

BY ALBERT S. ASHMEAD, M.D.,
OF NEW YORK CITY.

For twelve centuries the Japanese world knew no change. Buddhist traditions and doctrines, imported from India, religious laws and superstitions, held absolute sway. Even so far back as the age of Jimmu Tennô (660-585 B. C.), that fabulous first Mikado, who is said to have descended from the Gods, Japan had a theocratic form of government; the sovereign was not obeyed only, but worshiped. In the sixth century A. D., in the reign of the 26th Mikado, Buddhism made its first appearance in the country. It gradually extended its domain and consolidated its position through succeeding reigns, until, at last, the Empress Suiko (593-628 A. D.), recognized and made it the religion of the state. These populations have ever since been ruled by the doctrine of Buddha, and peculiarly moulded by its spirit. The Buddhist philosophy exposes, in its sacred volumes, a sacerdotal system of medicine for the cure of the body and the soul. From those hoary pages, Japanese medicine has been evolved; but ever since the twelfth century of the Christian Era, it has striven for independence, and by slow steps, reached, at last, a state of comparative freedom. For their speculation was never completely enfranchised.

All scientific teaching in Japan bears unmistakably still the religious stamp; as to statutory or civil law, it has never made even an effort to shake off the Buddhist shackles, wherewith it has been bound time out of mind.

The building up of the mental and moral type of the Nation has been the work of many centuries, and such a structure will not fall down at the trumpet-blast of one generation, nor of several generations. The laws here as elsewhere, have fitted themselves to national and individual requirements, and neither the spiritual nor the material constitution of the people can adapt itself, at least not for a long time, to the wants, feelings and aspirations of nations so profoundly different from itself, as those whom it has taken

now for its models and preceptors. It will be a useful preliminary, to devote a few words to the description of this strange society.

There have ever existed, it seems, three classes or castes in Japan, a hereditary nobility, a great middle class and a despised crowd of "Pariahs" and paupers. The nobility is composed mainly of the descendants of five ancient and illustrious families, the Fujiwara founded in 645-649 A. D., the Taira founded in 782-905 A. D., the Minamots founded in 839-880 A. D., the Hojo, a branch of the Taira, and the Ashikaga, a branch of the Minamots. The first three have married and intermarried constantly, even incestuously (through concubinage at least), during many hundred years, and thus kept all the power and wealth in their possession. From these are descended the court—nobles and daimios of the realm, the remains of feudal supremacy, whose power was overthrown only at the beginning of the Meiji era in 1867. The Mikado, or religious head of the Nation at that time, had abolished the Shogunate, or so called temporal power of the Tycoons, which had existed in a direct line for 264 years, having been founded by such members of the hereditary nobility as professed the greatest influence. Close breeding between families of that order has been the rule, and often, that families might not die out, it had been found necessary to recur to adoption. The same law which sanctioned adoption, sanctioned also the transmission of nobiliary rank by that process.

There are now 470 princes and nobles, and only 3,000 direct descendants of the old nobility. There has been 123 reigning Mikados, with one dynasty. In 662-667 A. D. reigned Tenji Tennô, the 38th Mikado, whose son became the head of the renowned family of Fujiwara (Wistaria field), next to that of the Mikado, the oldest family in Japan. In 898-930 A. D., in the reign of one of the "Puppet" Mikados, important and noble families arose who disputed with the Fujiwara family the control of the Mikado. In 931-946 A. D. reigned a child of the house of Taira. The great rôle of this family falls between the period of power of the Fujiwara and that of the Minamots, in the middle of the 12th century; and when that age of splendor expired, the name of the race continued to live in the five Sekkô families. The earlier professors of Tsushima and various other daimio families, claimed descent from the Taira. The Minamoto (Chinese genji, source of the spring) becomes prominent in its turn, and gives to the country its greatest and most celebrated heroes, who claim descent from the 52nd Mikado (806-809 A. D.). The office of Shogun, which was overthrown in 1867, became their exclusive property. Thus this family, through all kinds of vicissitudes, had held temporal sway during seven centuries! From the 62nd to the 74th Mikado (947-1108 A. D.), the in-

fluence of the Fujiwara continues. In the time of the 83d Mikado (1188-1198 A.D.), the Taira family power was destroyed, the female members were driven into prostitution, being allowed certain privileges, which have been handed down in that class to the present day. In 1203 A.D. the Hojo family appears, and is represented in the Mikado. This house of Hojo fell in 1333 A.D. In 1338 A.D. the Minamoto are represented in the Mikado. After the fall of the Hojo, the Ashikaga appeared, and for 56 years, there were two dynasties, one ruled by the Ashikaga and the other by the Minamoto. Their wars were called the wars of the Chrysanthemums; (this flower being the symbol of the sun, is emblematical of imperial authority—Nippon, the ancient name of Japan, means origin of the sun). The great Ashikaga died in 1409 A.D., and the power and the influence of the Minamoto, having declined from the time of the 102nd Mikado, gradually died out. In the second half of the 6th century, these families again renewed their supremacy, during the times of Mobunaga (of banished Taira and peasant blood), Hideyoshi (of pure peasant blood, and Iyéyasū (of Minamoto and peasant blood). These three names are the greatest in Japanese history. The Shogunate of Ashikaga ended in 1573 A.D. It remained vacant until 1603 A.D., when the Tokugawa dynasty (a branch of Minamoto) was invested with it through Iyéyasū, and continued till 1867 A.D., when it was forever abolished by the reigning Emperor Mutsuhito (Meek man,) whose mother was of the Fujiwara family through the house of Hujo. This Mikado, the 123rd of his line, has no child of his high born wife. It has therefore become a necessity of State to declare his eldest son by one of his six concubines, a lad now twelve years old, prince and heir to the throne. This ceremony will take place in the coming spring.

The great middle class of the population of Japan comprises the bulk of its people. Hybridity has been the rule with it through various immigration, invasions, wars and the commercial relations. Quatrefages (*Bull. Soc. d'anthrop. de Paris*, 1883, vi, 654) defines the factors of the population as follows:

1. A black element, type negrito, to-day probably quite fused.
2. A yellow element, coming probably from China, and always easily recognizable.
3. A white Olino element, representing the population which occupied the Archipelago, at the time of the conquest.
4. A white Indonesian element, which made that conquest, and which is found sometimes in a state of purity, especially among the members of the old nobility.

He makes Indonesian and Polynesian synonymous terms, which represent the same race,

claiming that the superior ethnological element, which peopled Polynesia came from the Malay Archipelago, in other words from Indonesia. This element M. Maquet tells us, is found in the part of the Japanese race, that is given to the traffics habitual to coast dwellers; he thus defines the nature of that ethnical element, to which belong the fishermen of Japan, so different from all other elements in the interior.

This Indonesian element is not autochthon, according to Quatrefages, but is represented by the conquerors, the tradition about Jimmu Tennō leaving no doubt in the matter. He claims that this Simili-Malay race was not a well defined race, but the result of the fusion of diverse, especially yellow and white elements, which were fused under the influence of Islamism. He thinks that the black element in the Japanese hybridity; is clearly negrito, and not Papuan or Polynesian negro, basing his conclusion on the study of the skull made by M. Hamy and himself (*Etude sur les Mincopies*, par M. DeQuatrefages, Revue d' Anthro. Les Negritos a' Fornié et dans l' Archipel. Malais, par M. Hamy, *Bull. de la Société d' Anthrop.* vii, Crania Ethnica).

Remy (*Bull. Soc. d' Anthrop. de Paris*, 1883, p. 908) observes that a blonde Japanese does not live, and he never heard of an albino. The blue iris is as rare as the blonde hairs; it had probably never been seen in the country previous to the advent of the Dutch, for the latter mention that they were called the "blue eyed Dutch." The black hue of hair, pileus and iris, is constant. This uniformity of hue, is, especially, the common tie of all the mixed hybridized races which form the population of Japan. The great majority of the people have a limited pileus development. The hair grows in abundance, but the beard, the hair of the pubis and of the arm pits, are rare, and the rest of the body is glabrous. This stopping of development of the pileus system, makes the Japanese preserve for a long time the appearance of adolescence. The same author states that there is no unique Japanese race, and that the population is a mixture of divers races.

His division of hybrid types is as follows:

1. Type with long face, eyes black, oblique and bridled, nose prominent and aquiline, hair stiff and abundant, beard rare, body glabrous. It is considered to be that of beauty and distinction, and is especially found among the nobility. Women who possess it are highly prized. (Mongol)?
2. Type with broad face, prominent cheekbones, eyes oblique, bridled, small, at the level of the head, nose flattened at the root, often prognathous superior jaw, black and abundant hair, the rest of the body glabrous or poor in hair. (Chinese).
3. Type differing from the two foregoing, by

its regular and horizontal eyes, without bridles, but preserving the broadness of the cheek-bones, the flattened nose, the yellow tint of the skin and the rarity of the hair. (Malay).

4. Type which approaches the European races by the disposition of the features of the face and the abundance of the pileus system. It is that of the Alinos, ancient possessors of the soil, driven to the wall by conquest, and living now in the northern part of the island of Yezo.

5. Finally, a novel element, the European hybrid, who takes as a rule the character of the occidental people, as to the shape of the eyes and the color of hair and iris.

Maget (*Journal d'Anthrop. de Paris*,) recognizes four hybrid races issuing from a dominant race. The Hamabêto (people of the sea-coast) forming the dominant race. It inhabits almost constantly the sea-coast, and is given to maritime occupations. It is a Polynesian race, red, with arched nose, eyes of small obliquity, short, as is everything belonging to the Japanese medium, whether animal or plant.

The hybrids of that race are in order of numbers:

a With the Mandchu-Coreans, more numerous in the regions of Nasa-Kendo, Sanindo and Hokuro-Kudo.

b With the Simili-Malays, more numerous in the island of Kiushiu and in that of Sikok. The race, noble, great (Koua zokou), and small (Chizokou), is usually connected with this type. It is the conquering race, and rules to this hour.

c With the Ainos. This branch, frequent in the Ken Akita and the Nambou, does not seem to pass beyond the banks of the Biwa lake. In the north of the island of Nippon, the hybrid Olino-Polynesians are rarely found apart from the sea-coast.

d With a black population (Negrito Polynesian blacks?) This branch of hybrids, which has only few representants, is distributed with some uniformity among all classes. It is recognizable by the Negroid appearance, the sombre and often blackish hue (the Arab negro hybrid tint of Algiers), the curling of the hair or their repeated undulations, the gracility of the calf which is very developed in the autochthon (?) race, finally the relative smallness of the stature. (Mr. Maget describes and figures patches and points of black pigment which appear pretty frequently in the sclerótica of all the Japanese races. He sees in these spots an atavic trace of an ancient mixture of negro blood.)

These hybrids have not, in the country, any fixed point of concentration.

Pfoufou (Transactions of the Asiatic Society of Japan) says: "The Japanese were never a conquered nation; immigrations peaceably occurred by several different routes (the Malay Archipelago, Corea, Kamschatka and China);

they bore a prominent part as a nation in the wars of the Indian Princes on the Malay peninsula, and thus fell in with the Arabs, who, before the sixth century, had gained a foothold in China. With them they voyaged to India and Africa. He observes also that there are many different types of men in various localities of Japan.

Brinton says: "The population of Japan is distinctly of mixed origin. The Mongolian and perhaps the Negrito, united with the Aino to produce it. And of what affiliation is the Aino? We cannot say. The Negrito or Eta people are, I believe, the primitive inhabitants of Indonesia, the Malays, etc., later arrivals. Whether these blacks reached Japan, or even Formosa, is rather doubtful, though some have argued in favor of it." He further says: "I am persuaded that island life exerts a more rapid influence, both on physical and linguistic traits, than continental life."

Faulds (Nine years in Japan) observes: "Regarding the affinities of the Japanese, we have no certain knowledge. They are 'Mongrels.' Excluding the Ainos, they are a great ethnic fusion to be further studied. They claim to have descended from heaven, and I hope they may all get back there again."

In our third great division of the people, are included the vast hordes of "Pariahs," the paupers, beggars, and lepers of Japan.

Originally, as is supposed, this class consisted of the Eta, the despised negroid element of the Japanese. The Emperor Tennu Tennô (672-686 A.D.), issued an edict against the use of animal food, which had previously been restricted at the first appearance of Buddhism in the country. This edict was probably instigated by the Priests, whose creed especially forbade the taking of life. Hence tanners, curriers and all leather workers, became "Pariahs." The Eta alone, the original "Pariahs," earned their living by working in skins, and converting them into leather. They also gathered lamprey or loach, which they sold on the bridges, about the moats and canals, which pious Buddhists would purchase, and liberate, by throwing them over the parapet into the water. This act of devotion was called Hojoji, and the Eta, in their capacity of beggars, would offer up prayers for the welfare of their extraordinary patrons. The Japanese Encyclopædia (San-Sai-Dzu-Yé) explains that "the Eta were originally 'Etori,' or attendants, who killed animals required for feeding the Imperial falcons. The Buddhist priests interdicted this unfortunate people's sharing fire and shelter with the rest of the population, and thus the Eta came to constitute a separate race," and thus, possibly, they were subsequently refused privileges of intermixture with the various immigrations that contributed to produce national

hybridity. The "Hinins" (not human) were a class of paupers after the commencement of the Tokugawa dynasty (1603 A. D.). They were allowed to squat on waste lands, to build huts, and gained a livelihood by begging. They were employed to carry away dead bodies from the execution grounds. All of these sub-classes, Eta, "Hinins," "Pariah," beggar, have always been the associates of lepers, and are the more utterly despised. As I have stated elsewhere (Leprosy in Japan—Intermediary—host function in its propagation. *Cutaneous and Genito-Urinary Journal*, 1890), when leprosy attacked a member of a family, he at once strayed away, before his neighbors could know of his misfortune, and wandered, in beggar disguise, to some distant part of the Empire, that he might hide himself among the Eta. This was done, that the other members of his family might not become socially ostracised, or be refused marriage and communion by the neighbors, leprous taint, in bride or groom, being an absolute barrier to union. All beggars, therefore, were outcasts; they could neither eat nor sleep in any man's house, but only under trees, or in abandoned sheds. A dish that was once passed in alms to a beggar, was afterward destroyed, and the vessel from which he had drunk, was not used again. Should he wash himself, perchance, at a well or public watering place, that water became, in public estimation, polluted. Hence the mendicants and despised classes, were forced to make use of streams, rivers and pools; and these were in consequence avoided by the more fortunate.

There are in Japan, according to estimate, 3,000,000 Eta, all, more or less, destitute. They officiate at executions of criminals, burials of dead bodies, and Buddhist cremation ceremonies. Griffis (The Mikado's Empire) very graphically refers to them, in his relation of a visit to the Crematorium at Fukui: "On the other side I saw a great heap of skulls, bones, clothes, bowls, utensils and other relics of the dead. It was the monument of a famine, which ravaged Echizeu some forty years ago, and during which the poor and the beggars died in such numbers, that they could not be consumed or inhumed in the usual manner, that is, singly, but were cremated by scores, on heaps of brush wood. Near the house was a mound, containing many thousand cubic feet of ashes and calcined bones, the refuse, incineration of the furnaces during many generations. It was "ashes to ashes" instead of "dust to dust."

As for the living "beggars" to be met with in Japan, he says: "We cannot understand their chabu, komarimasu tempo, danna-san, dozo (please, sir, a penny, we are in great need of food), but we comprehend the object of their importunity. They are loathsome, dirty, ragged, sore. Now I wish I were a physician, to heal such

vileness and suffering. Who would care to do an artist's or a poet's work when the noblest of healing needs to be practiced? The children run after us. The old beggars live in straw-kennels, by the road-side, some are naked, except dirty mats bound around them. The law of Japan does not recognize them as human, they are beasts! The man who kills them will be neither punished nor prosecuted. There lies one dead in the road. No! can it be? Yes, there is a dead beggar! and he will lie unburied, perhaps for days, if the dogs do not save the work from the coroner (?). 'And the beggar died;' will he be carried to Abraham's bosom?' These three classes have, during many centuries, lived very much apart from each other. Yet their alimentation was not so different as such a state of things would lead us to suppose; indeed, it has almost been nearly identical through the whole of Japanese society. The climatic influence was the same for all. They have been exactly in the same degree exempt from certain European diseases: puerperal fever, scarlet fever, diphtheria, endemic measles, etc. (in Japan measles occurs epidemically and at long intervals. I saw none. In 1876 and in 1882 separate epidemics occurred). It seems strange, therefore, the conditions being so equal, that the two great diseases, tuberculosis and leprosy, should be almost monopolies of special classes. Tuberculosis is the scourge of the aristocracy, the closely in-bred race of Japan.

Not that it spares the rest of the nation by any means; but it is to the lower classes singularly more merciful. In the high and inbred race the tubercular disposition, tainting and modifying every other disease, is really destructive, so much so that many strains of noble blood would have been extinguished long ago, but for the laws providing for the substitution of heirs. And this tainted tubercular race is a standing menace to the nation's blood, constantly inoculating it through concubinage. In strong contrast with this aristocratic pestilence, leprosy is the disease of our third class, the great crowd of pariahs and paupers. Between these two orders of Japanese society, afflicted each with its own peculiar malady, is situated the great middle class, a hybrid multitude, with no customs of close intermarriage, with active avocations; they are between the drones of high and low life, the workers of Japan. The privileged position of the upper class in regard to leprosy, I am disposed to consider as a fact, partly from personal observation, partly from information derived from native colleagues. In this conclusion I am corroborated by the testimony of foreigners also. Baelz (*Beiträge zur Lehre von der Lepra*, Tokio, Japan, 1885), treating of the matter, says: "A leper belonging to the upper classes I have never seen; one meets, however, as Dr. Miyake assures me, sometimes very rich lepers. For, in deference to hoary Jap-

anese tradition, marriage with members of leprous families is discountenanced, while the lepers intermarry unrestrainedly among themselves. As they are loath to be seen, they retire among their own people, and try, by the acquisition of wealth, to obtain at least such comforts of life as can be got for money. However, these are rare exceptions; most lepers are in wretched circumstances, and many of them subsist miserably on the proceeds of mendicancy upon the high roads or around the outskirts of popular places of pilgrimage. If we believe some Japanese data, the much despised and severely shunned class of the Eta suffers much more frequently from leprosy than the rest of the population." The same writer further observes: "That a manner of living, at variance with the laws of health, favors the eruption of the disease, is admitted unhesitatingly by all observers. The more wretchedly men live in the leprous countries, the more readily they fall a prey to the scourge. We have mentioned before the frequency of leprosy among the Japanese pariahs, the Eta, who, up to quite recent times, used to live in isolated hamlets, and with whom no man held any intercourse—a vessel they had used, anything that had been touched by them, was polluted. Nothing positive is known as to the origin of the Eta and the motive of their isolation. I think it probable that they are the descendants of leper colonies. A circumstance which points very decidedly in that direction, is that the idea of uncleanness, as the Hindoos conceive it, in regard to the lower classes, is quite foreign to Japanese conceptions."

Wernich (*Ueber die Etiologie, das Erlöschen und die hygienische Bekämpfung des Aussatzes*, Tokio, Japan, 1879) says: "If we turn to the conditions to which a hereditarily disposed individual, born in a climate which influences unfavorably the activities of the skin, is further subject, we cannot omit to cast a glance, in the first instance, on *race and nationality*. There could, of course, be no objection to our treating of the relations of races also, in the section where we speak of the heredity of leprosy. However, it will appear that the conditions of development contained in the race type, are less important for the production of leprosy, than those which touch immediately the vital relations. The disease, as well in Africa as in the Western hemisphere, is much more frequent among the colored races than among the white. In the East Indies, where the European residents fall very seldom a prey to it, all indigenous colored races are equally threatened by it; especially the Eurasians (the Anglo-Indian hybrids) furnish their very considerable contingent. In Southern Africa, the Hottentots are most involved, the Negroes follow, the whites are the most leniently treated. However, the supposable immunity of the European ceases, as soon as he lives in countries where the disease is at

home. These circumstances suggest, for this point too, a taking into account of the skin system. That the latter is more disposed to disturbances of nutrition, more vulnerable, in colored races, is already made probable by the pigmental element, and it is approximately proved by the immense frequency and variety of the skin diseases to which all colored races are liable. But the acquired disposition of the European, which we have mentioned, finds also on this ground its most natural explanation. The violent alterations to which the skin of the European is exposed through profuse sudoral excretion, through the heat-rashes, through melasmata and general discoloration of the complexion, can, after a long time and accumulation, very well be designated as directly destroying influences. True, they display special vigor only then, when the European has to do without the preservatives which his *a priori* privileged position in foreign parts secures for him—when he must, as regards his social position, his life comforts, the care of his health, un-Europeanize himself. The troubles and injuries which present themselves to view in this connection, are, for the etiology of leprosy, of different value. *Much the greatest part of the leprous cases belong undoubtedly to the lowest and poorest layers of society.* If against this it is asserted that there is in Europe, in every country of it, an unleprous proletariat, exposed to all the injuries which hurt the body, and the skin especially, some grounds for the belief in the amendment of the general conditions of the lower classes will be found, nevertheless, when we shall examine the extinction of leprosy. High prelates, princes, crowned heads, were attacked with leprosy in former centuries; certainly those did not suffer most of the evils under which the lower classes are laboring. To the description of squalid misery, prevailing in some regions in Italy, Portugal, Spain, etc., has been opposed the fact, that some neighboring leprosy-free villages and communities present nearly the same wretched conditions of life. But these objections lose much of their weight, if we keep in mind that the eruption of leprosy results surely from a concurrence of various causes, that a life passed in ease is probably not sufficient to obviate the consequences of a decided hereditary tendency in all cases. The majority of the cases of the high-placed rich lepers become preëminently clear, by a certain *modus* of acquiring the disease. While giving due weight to the objections made, we retain here the fact, *that the habits of life of the richer classes are generally a protection against leprosy, while the habits of life of the lower classes provoke the disease.*"

The portion of the lower class which bears the largest burden of leprosy—which is, so to speak, a vast human sewer, cleansing the upper regions of the nation, is scattered over the whole Japanese world. While the noblesse has been stag-

nating for ages, the lower set have been indefatigable wanderers upon the face of the Empire; friendless, lawless, starving, without shelter. In this social solitude, separated from all those offices of kindness and legislation which society affords to the other classes, they were reached by the Buddhist religion, comforted, fed, controlled and administered by it. Under the influence of that creed arose the whole system of customs and traditions governing leprosy. The all-pervading salutary rule of the Buddhist religion is illustrated in the following legend: Chiba-Ken, in the south of the Empire, is a sort of Mecca for the lepers. In many of the story-books we find related that, over a thousand years ago, there lived in that place a youth, twenty-one years old, who was stricken with the popular disease. He was loathsome to behold, and his physical condition repelled all his friends. In this sad plight, he dragged himself to the Temple of Naruba-Fudo, asking to be relieved from his horrible distress; and, to show his good faith, said that he would abstain from food for twenty-one days. After the expiration of twenty days, and in the middle of the twenty-first, Fudo appeared in the flesh to him, and graciously kissed the poison from his sores. Thus was the young man's health restored. The relief was so overpowering, that the quondam leper thought that he must be on the threshold of Nirvana; his rapture was so great, the feeling of gratitude so strong, that he resolved to do nothing but good henceforth. So he became a Buddhist anchorite, and eventually a shining light in the church. Fudo is said to be a double being, a combination of God and Buddha, and is represented, in many temples, with three faces and a body standing, phoenix-like, in the middle of a blazing fire (showing him to be the representant of a divine element of purification, for fire is to them the emblem of purity).

In the province of Sanuki, situated on a peninsula about 700 miles south of Yedo, we find a great multitude of these pariahs and lepers, the Japanese generally believing that the lepers who betake themselves to the immediate protection of Kon-pira, whose shrine is there, will be cured through his tender mercy. This superior being is at the same time God and Buddha. The climate of Sanuki is remarkable by its mildness and amenity, the province being nearly encircled by the sea. Almost all the lepers in the Empire, at some time of their lives, gravitate toward that holy region, and make there a stay of more or less duration. It was a medical teaching of the Buddhists, that a leper should not remain stationary in the place in which the disease had originated. Hence the roamings and disappearances of lepers. Most of the leper laws of Japan are Buddhist traditions, as unchangeable as the laws of the Medes and Persians. The Japanese firmly believe in Kon-pira's power to cure lepro-

sy, and to this popular belief, as well as to some others of Buddhist origin, is due the segregation, and, to some slight extent, isolation, of this wretched multitude. He is, in the Roman Catholic sense, the patron of lepers; he takes care of them in every way. If a leper is robbed in Sanuki, he will compel the thief to restore his booty.

It is estimated that there are in Japan over a hundred thousand lepers and suspected lepers, mostly in the southern part of the empire, but distributed in various proportions over the whole country. There is no belief whatever in its contagiousness, nor in its sexual infection. Whence it came and how it originated no one pretends to know, although it is so common in the southern provinces, where syphilis also is rampant, and the temperament of the population lascivious in the extreme; yet the medical mind of Japan—that is, her physicians and priests—has not been led by this simultaneous presence to admit a congenial nature of the two diseases; on the contrary, they deny it most decidedly, and the proportions in which both diseases affect the different classes bear out their conclusion, for syphilis is more frequent in the middle classes than tuberculosis or leprosy.

The leper class of Japan is not the product of heredity, as their traditional class segregation of outcasts would have operated to destroy the taint; for it is generally recognized, at least in Japan, that the disease exhausts itself after five generations.

Let us pass now from the disease which squalid misery fosters among the poorest of the nation to its aristocratic rival, which the inbreeding of the upper classes favors in a different, though little less disastrous manner.

Remy, in *Arch. Gen. de Médecine*, makes the following statement: "Tuberculosis is not rare in Tokio (Yedo) and Yokohama; as usual, it is more frequent in the city than in the country, and, among the denizens of cities, it affects especially certain classes—*people who have no muscular exercise—the nobility*, the merchants, all who are given to study or have a sedentary profession. There exists between the inhabitants of the country and those of the city a difference similar to that which exists in our own countries. The former owe to the labors of agriculture a more complete muscular development. They are broader, more massively built. In Japan the tilling of the soil is entirely done by man's hand; the beast of burden is little used. It is man who breaks the glebe, carries the burdens, drags the loads. It is the same in the city with laborers. They are strong and muscular; but some of them have begun to indulge in drunkenness, and to get intoxicated with the rice brandy, the saké.

The city man is of weak constitution, and has attenuated limbs. He often lacks every bodily

exercise. Gymnastics, games, equitation, are not valued. The nobles have given up their practice of arms. The merchant, in his wide, open shop, the student in his chamber, remain motionless for hours. Nutrition, in consequence, is badly performed, and in winter the heating of the apartments is quite insufficient. A few coals in the middle of a vessel filled with ashes, the 'hibatchi,' or brasers, is the only system known. Insufficient in a space enclosed to the extent of two-thirds of its periphery by slight wooden frames, which are covered with translucent paper, this 'hibatchi' is perfectly useless in a shop, constantly open in all the breadth of its façade. The poor merchants crouching over their 'hibatchi,' their hands extended over the coals, offer a spectacle truly pitiful. Their clothing itself is little calculated to protect them against the cold. It consists, for both sexes, of dresses open in front and tightened around the waist by a girdle. The shirt is used by those who have come in contact with Europeans, and even by them seldom. A simple piece of stuff goes around the loins and extends to the middle of the thigh. Buttons are unknown; so that the dress, simply crossed and kept in place by the girdle, leaves uncovered the upper part of the chest, and leaves bare the legs also at every motion. The men wear sometimes cotton drawers, or tight breeches of blue linen. In the country, women wear a similar kind of inexpressibles, which makes them look like men; but in the cities, the legs of women remain uncovered. A simple, small linen sock covers the foot up to the ankle. Moreover, the air penetrates to the skin through the large orifices of the sleeves. To this inadequacy of defensive armor against the cold must be attributed the frequency of the pulmonary affections, bronchitis, pleurisy, catarrh. However, in Tokio, pneumonia is comparatively infrequent, even among laborers. As to tuberculosis, it must be referred to as complexity of causes: the insufficiency of bodily exercise, of the heating, a diet often too scanty, often excess in pleasures, to which the Japanese are uncommonly prone; finally, scrofula (?) and hereditary disposition. However, I am of opinion that there exists among the adults a good deal of acquired phthisis. The tuberculosis potatorum is almost unknown. There is only one alcoholic beverage in general use, the saké, or rice brandy; it induces intoxication rapidly, but as its daily use is not common, there are but few drunkards.

Tuberculosis, then, is either hereditary or acquired. It affects every age, children, adolescents, mature men. I have often seen it start with the left side of the lungs, as it is observed to do in the tuberculosis incident on sedentary avocations. Here are some particulars: it begins sometimes with exudatory peritonitis, whose products are resorbed, as in pleurisy. It is less

frequently accompanied by digestive disturbances. The ingestion of the saké causes almost always abundant hæmoptysis."

Wernich (*Infections Krankheiten der Japanesen*, Tokio, Japan, 1878) speaks of the enormous frequency of tuberculosis in the Japanese islands. "The most important atmospheric element for its favorable course," he says, "is the low degree of atmospheric humidity. Next to dryness, uniformity of temperature must be considered as the most important element to secure rarity and a relatively better course of the diseased phenomena. A uniformly low temperature is, in this respect, to be preferred to a uniformly high one. After comparing these conditions with the element represented by the Japanese climate, it will not seem strange that in our about 2,200 cases, tuberculosis alone was represented by one-seventh, 325."

In speaking of the course of the disease, as exhibited to him in these cases, he points out the frequency and abundance of the blood effusions in them, *exceeding all limits known to him*. "In the freshly observed cases appeared the very remarkable symptom of a dark red coloration of the sputa, enduring for weeks, sometimes amounting to a regular hæmoptysis, *without any bad results ensuing*."

Herein Wernich evidently counts his cases of distoma pulmonale (Ringeri) with consumption. His percentage of ordinary middle class tuberculous cases would be otherwise excessive.

Baelz (loc. cit.) says: "The analogy between leprosy and tuberculosis, which we have repeatedly pointed out, is important enough to warrant a little more consideration. The bacilli of both diseases are distinguished by quite a number of common peculiarities, which differentiate them from other bacilli. Both diseases are probably contagious, but in a very feeble degree. In both the danger of infection diminishes in good hygienic conditions. Leprosy has a great deal of similarity with skin tuberculosis. Leprosy and ulcerous tuberculosis of the lungs affect seldom children previous to puberty.

At any rate, the two diseases must be considered as congeners, and it would not be without interest to examine whether there does not exist between them such a relation, *that in countries or in classes, where the one is frequent, the other is proportionally scarce*. As far as my knowledge of the literature enables me to judge, tuberculosis hardly appears to have played formerly the same part which unfortunately it does in our day."

He further remarks: "It is with tuberculosis that leprosy has the greatest analogies. Although every physician will concede now-a-days that tuberculosis is transmissible, experience shows, on the other hand, that for a large majority of mankind such a danger does not exist, in spite of most intimate intercourse. In order that a

man be affected with tuberculosis, the presence, and even the reception, of the bacilli is not sufficient, otherwise every physician and every nurse would be tuberculous. The point is, that the bacilli find a *proper soil for their nutrition*; and *this favorable soil consists in a mostly hereditary weakness of the tissues*. In a strong man, the cell devours the bacillus; in a weak subject, the bacillus devours the cell.

In this sense, *heredity is still of the greatest influence in the origination of consumption.*"

I came myself for the first time in contact with Japanese tuberculosis in 1873. I was then called from Philadelphia to attend Prince Adzuma, a brother of the Mikado, who, under an assumed name, had been studying at the United States Naval Academy, at Annapolis. He had been seized with a hæmorrhage of the lungs, and was removed to Wormley's Hotel, Washington. Dr. N. P. Lincoln, in consultation, after the incipency of tubercle had been determined, advised the transfer of the patient to New York, for examination by the elder Flint, who directed his removal to his native country. I afterward saw him at his home in Yedo, and found that the disease had steadily progressed. He died in the following year. It has been my experience among the Japanese to find this disease most active among those people who take the least exercise—the higher classes, the nobles, the rich, the studious, and those given to the vices of high life. That, as we ascend the social scale of Japan, the general weakness of the constitution increases will be made evident, I think, by the well established fact that the court nobles and daimios do not produce much offspring. While, in the middle classes, four children to one mother is the average, in the daimios' class, one is the rule. This scarceness of progeny cannot, by any means, be ascribed to a want of sexual appetite. The Japanese are an amative race, and the Yoshiwara or prostitute system had to be instituted to restrain the passions of the Shizoku, or military nobility (the order next in rank to the hereditary nobility). Neither Shintoism nor Buddhism had proved adequate to the task of keeping them in bounds. Hence, public morality had to make concessions, and society gave its countenance and approval to the marital union between the representatives of society and those of that same Yoshiwara. It came thus to pass quite naturally that mothers sold their daughters to the brothels in order to give them a chance in life! Their sexual perversities are many. Pederasty and other unnatural vices are as common as in any country of Asia. In the northern portion of Nippon, Mutsu, composed of several noted provinces, and in famous Satsuma, in the south, there especially the "Millstone of Orientalism" hangs around the neck of Japan. The love of "bichonen" (fine boys) is a part of the aristocratic tra-

dition. The last great insurrection in Japan was notoriously complicated by the jealousies of two statesmen about a beautiful youth. These vices have helped to weaken the race.

Maclay (Budget of Japanese notes), speaking of the daimio of Hirosaki Castle, says: "During the hot summer months, when the exhalations from the moat render the immediate vicinity unhealthy, he will journey off to his mountain villa, where he can spend a month or two in composing Chinese poetry in honor of the moon or his favorite concubine. About three or four times in season he will exert himself sufficiently to visit some hot mineral springs in the mountains, to soak out the licentious impurities of a past winter." And, speaking of the Samourai, or military nobility, not included in the hereditary nobility, but who are attendants on it, he says: "The truth is, about Perry's time, political affairs in Japan had become thoroughly run down. These Samourai were rapidly degenerating into a herd of voluptuous imbeciles. Licentiousness abounded in private life."

We can clearly see now, how this excessive inbreeding of an originally finely bred race, through so many generations, added to a luxurious life, in which every wish was gratified, and vice fostered in an unusual degree, the existence of a pampered aristocracy, obeyed and corrupted by that servile military order, always cringingly at its beck and call, until it had almost sunk into imbecility—how these conditions worked together to bring about the disposition to the disease, the tubercular soil. The whole order has thus become eminently susceptible to this special disease.

Holmes (origin of the Infectious Diseases, Jour. Am. Med. Assoc. 1890), says, regarding the bacillus of tuberculosis: It appears that it is unable to grow on any accidental or artificial media, under any presumptuous natural conditions of temperature and external surroundings. It is able to multiply in man and in some other mammals, and in a few related vertebrates. Therefore, we may presume that, should it be deprived of a living host, even a day beyond the few months during which its spores might retain vitality, the species would become wholly extinct, and the world be free ever afterwards from the ravages of this dreadful scourge. The bacillus of tuberculosis is then an obligate parasite of the warm blooded animals. When we consider what specific difference means, and how perfectly the bacillus of tuberculosis manifests this difference, and when we see how great is its geographical distribution, we are compelled to go back far into the present geological epoch, and probably beyond it, for its origin."

He further says: "Looking upon these obligate parasites of man, as of such ancient association, going back beyond the present geological epoch

for the beginning of *syphilis*, *tuberculosis*, *leprosy*, etc., how is it possible that man has been able to withstand the attacks of so many enemies, for so long a time?

The very fact that he has survived, and that these parasites are unable to exist in any other media, than his living body, is conclusive proof that they are not essentially destructive parasites; for with destruction of the host species, occurs the destruction of the obligate parasite. Such a proposition appears to be axiomatic, but axioms occasionally need to be formulated. Given abundant opportunity of contagion, a destructive obligate parasite is inconceivable. It is possible only when its destructiveness does not interfere with the reproduction of the host species, as after the reproductive act has been performed."

And further: "While we are accustomed to look upon *syphilis*, *tuberculosis* and *leprosy*, as excessively destructive diseases, a moment's consideration is enough to clear our minds of this traditional notion. Syphilis, in the strong and healthy Caucasian, frequently runs the first and the second stages of its course, without recognition, and does not, therefore, interfere with procreation. When the infirmities of age confine the patient to unfavorable surroundings and habits of life, the tertiary symptoms come on with the reduced vitality and nutrition. Fatal or destructive syphilis, in the otherwise well and healthy, is rare. In children and in poorly nourished young people, and in those suffering from chronic diseases, it frequently appears as a terminal affection."

"Tuberculosis in the lymph glands of the neck, in the bones and joints, in the ear, and even in the peritoneum, is not very destructive. It is frequently followed by recovery. Even in the lungs, tuberculosis may run a chronic and rather harmless course, and interfere very little with the reproduction of the species. It is only after pyogenic infection of the tubercular tissues of the lungs, or other areas, that sepsis and symptoms of "hectic" appear. This sepsis is then the destructive factor, as it is in wound infection."

"Leprosy is the closest obligate parasite of man, so far observed. The *bacillus of leprosy* bears a remarkable morphological relation and staining reaction to the prime factors of *tuberculosis* and *syphilis*. It is almost never a destructive disease, and it appears only in those who could have already accomplished the reproductive act; therefore it does not interfere with the perpetuation of the species. It is conveyed by contact, but only with difficulty, and there is evidence that it is not necessarily hereditary; that is to say, healthy children may be born of those who are suffering from leprosy. The attendants on persons suffering from leprosy are not often affected with the disease, but often enough to demonstrate its contagiousness(?)."

Finally he remarks: "*Leprosy* conveys no immunity, for the disease rarely terminates in recovery, but the infection is accomplished with the greatest difficulty, and the spread of the disease is slow. *Syphilis* is not very destructive, it has a difficult but certain method of infection, and one attack does not so surely protect against subsequent recurrence. Instances of this kind could easily be multiplied, bringing in other factors, which act in producing immunity, or protection, or physiological resistance. *All brought about by the obvious necessities of the law of the survival of the fittest, and that of heredity.*"

His conclusions are:

1. All obligate parasites are without exception, examples of *very ancient parasitism*, and what is of more practical moment, they are necessarily non-destructive to the host species.

2. *The destructive action of the obligate parasites is only manifested toward the weaker individuals of the race, and therefore they are a factor in the evolution of a strong and wise and morally temperate nation.*

3. The great field of expectant medicine lies in the treatment of diseases, due to obligate parasites, while the great field of preventive medicine is to be found in providing against infection with facultative parasites.

It is strange that these three obligate parasites of man, dating back probably to a mythical age, should have thus occupied each its own almost exclusive domain in the Japanese nation.

It seems as if the division of this nation, with its varying conditions of conjugality, has exercised a strong influence upon the development of these three diseases, which have so many congenial features.

Whether there is any value in the points which I have here endeavored to elucidate, whether they are of a nature to throw some light upon the portions of ethnical pathology to which they refer, I leave it for the decision of those who are in a position to speak with superior authority on these subjects.

The most important conclusions, I think, to draw from the facts exposed in these pages, are:

1. The close in-breeding of an exclusive class tends to its destruction, through the development of a tubercular soil, or through sterility.

2. Hybridity, as shown by a negative proof in the highest class of Japan, is a requisite for the formation of a healthy race, (with but one exception, represented by negroid element, as in the Eta of Japan); the mixture of races is therefore greatly to be approved of; it is one of the great elements of strength in our American nation.

3. As nature tends to eliminate, by her own occult operation, tubercular and leprosy elements, from the healthy mass of the people, our only rational course is to assist her, by *isolating our tubercular patients*, as lepers are isolated in other countries.

ELASTIC LIGATURE IN INTESTINAL ANASTOMOSIS.

BY A. H. CORDIER, M.D.,
OF MCPHERSON, KAN.

There are not many surgeons in this country who have not, at some time within the last three years, done some experimental intestinal surgery, and the number of dogs sacrificed for the "advancement of science" are counted by the thousands. In no other way could this rapid advance have been wrought in so short a period. To Dr. Senn is due the credit of this desire to improve in the technique of intestinal surgery, and the advent of his decalcified bone plates marked a new era in this branch of our healing art.

The many modifications of his plates by eminent surgeons suggest to the reader's mind that something better is desired. The catgut mats and plates of Davis, the segmented rubber rings of Brokaw, and the plates of vegetable tissue of Dawbarn, are a few of the many methods devised by various surgeons, all of which I have used in my experimental work in the last two years.

When we recall the old and tedious method of joining the divided gut end to end, occupying an hour and a half of valuable time, well we may with joy herald the introduction of any operation which will reduce to a minimum the time of performing it, and thus rob the operation of one of its greatest dangers.

At the last meeting of the American Medical Association, the address on surgery was delivered by Dr. T. A. McGraw, of Detroit, selecting as his subject, "Use of the Elastic Ligature in Surgery of the Intestines." On reading the article in *THE JOURNAL* of the Association (May 16, 1891), I resolved to begin a series of experiments on dogs by this method, as described by Dr. McGraw. I sent to Milburn and Williamson, of Detroit, where the elastic ligature may be obtained at a trifling expense. By the 25th of May I had begun my work. The ligature is about the size of the lead in an ordinary lead pencil, very elastic and stout. By shaving the end of the ligature, it can be threaded on a needle much smaller than itself.

I quote Dr. McGraw's language as it is published—that is, that part of his paper describing the application of the ligature. "This is a decided advantage, for the reason that it is important to make as small a hole as possible through the intestinal wall, and also to have the ligature not only completely fill, but distend the hole, so as to prevent any extravasation of feculent fluid. Now, by stretching the rubber during its passage, rendering it thin and small, it may be easily drawn after the needle, and its subsequent contraction will largely increase its size and cause it to more than fill the orifice. The ligature was in most cases passed through the gut in its long axis and

at points most distant from the mesenteric attachment. Before passing it the bowels were stitched together by from three to six Lembert sutures, and afterwards similar stitches above the ligature served not only to give additional protection, but also to bury the rubber in the intestinal folds. Usually an inch or more was included in the ligature. After the cord had been drawn through both coils of the intestines, it was tied as tightly as possible in a square knot. Although the knot will ordinarily hold without further fastening, yet, as I wished to cut the ends very short, to cause as little peritoneal inflammation as possible, I always secure the ends so as to make slipping impossible. In tying the ligature, a silk thread is laid under it, first over the first turn of the knot and afterwards over the completed knot—this fastens the rubber against a possible slipping. In making the knot, the ligature should be drawn as tightly as possible without breaking."

In my experiments on fifteen dogs, I did not lose a dog from any cause. Antisepsis was observed as thoroughly as possible. My dogs were killed at various periods after the operations, and the results noted. I found the same condition of the effects of the ligature as described by Dr. McGraw. My dogs, rapidly recovering from the immediate effects of the operation, were up and eating in a few days.

In this short period, and with the very limited experience in doing an intestinal anastomosis by the elastic ligature, I am very favorably impressed with the method, and have made the following deductions:

1. It is an emergency method.
2. The ligature does not swell and produce undue pressure on any other structures than those intended to be cut through.
3. It is not acted upon by the alimentary juices, consequently cannot disappear before its work is completed.
4. It can be used in establishing the lumina of the gut in closing an artificial anus.
5. You do not get needles and threads tangled, as is liable to occur in applying any of the ring or plate devices.
6. Requires less experience and fewer assistants.
7. Does not open the gut until after plastic exudate has sealed the approximated surfaces, thus avoiding one of the greatest dangers in other anastomotic operations.
8. It is quickly performed, saving from fifteen to thirty minutes of valuable time to the patient.
9. The elastic ligature is so pliable and soft that no harm can possibly come from its presence in the intestines.
10. By using the elastic ligature and surrounding it with Lembert sutures, you bring and hold in contact as large or larger surfaces of peritoneum than you can get by any other operation.
11. The opening made is lined by mucous

membrane throughout, thus insuring its patency.

12. You do not produce any hæmorrhage from dividing the vessels of the intestines, as is often the case in using the plates or mats. This bleeding, although easily controlled, takes up some time to check it in many cases.

13. Its use is limited, and may be applied where there is a partial stenosis of the gut, or destruction in part of the intestine which will lead to a stricture if repaired. In the latter condition, the rent may be closed with Lembert sutures or resected, the ends inverted and closed in the usual way, and approximated by this method, and a communication will be established in four or five days.

14. This method finds special indications when an operation for cancer is performed, or for sloughing intussusception or hernia, stricture of any part of the intestinal canal where the obstruction is not complete or of long duration. All cases demanding an immediate relief by establishing the continuity of the canal, or within a period of four or five days, must be operated on by some one of the other methods.

15. Where it is necessary or advisable to make a large or long opening, as in operating on the large intestines, to prevent too much puckering of the walls of the gut, a double ligature can be applied, upon the principle of the "Tait Staffordshire knot," or the chain ligature of Dr. Peaslee, taking care to tie the ligature so the knot will come in the middle of the constricted and approximated surfaces, and is well closed in by Lembert stitches.

I recall one case in the human being in which I applied the approximation mats of catgut for the relief of a traumatic stricture of the ileum, the patient dying from shock a short time after the completion of the operation, I believe in part due to the almost unnecessarily prolonged time occupied in making anastomotic openings, introducing mats, untangling threads, want of more experience and skilled or trained assistants, all combined, taking up much valuable time. With the elastic ligature operation I believe this case would have recovered.

Dr. McGraw, in his able address, has left so little unsaid of his method and its results, that I refer the reader to his article.

I desire to thank Dr. Salthouse and Mr. Tull, a medical student, for valuable assistance rendered while carrying on my experimental work.

IN EVERY case of hysteria, whatever be the condition of the locality giving rise to the special symptoms, there is a pathological condition of the central cortical cells, and to these you must address your attention if you hope for success in the treatment. You cannot afford to scout the idea of disease simply because the peripheral lesion does not correspond to the symptoms existing. Disease just as important and far more troublesome is present, and will require the skill of the most expert for its mastery.—*Lancet Critic.*

SALPINGITIS; WITH A REPORT OF TWO CASES.

Read at the Forty-sixth Annual Meeting of the Ohio State Medical Society, Sandusky, O., June 17, 18, 19, 1891.

BY A. B. WALKER, M.D.,
OF CANTON, OHIO.

It has been but a few years since we have known much regarding diseases of the Fallopian tubes. Thirty-three years ago Bernutz, in his writings, clearly described the pathology of pelvic inflammations. But little advance, however, was made until Mr. Lawson Tait, in 1872, made known his remarkable success in removing diseased tubes by laparotomy.

The writings of Battey, in America, and Hegar, in Germany, on the removal of ovaries for other diseases than that of ovarian tumors had much influence in developing the proper method in treating diseases of the uterine appendages.

It was not until 1882-3 in America that the operation of laparotomy was made for removal of diseased tubes, the first operator being W. Gill Wylie, of New York.

During the years 1883-4 numerous cases were operated upon for salpingitis by gynecologists and surgeons, since which time the operation has been very frequently performed.

Previous to the investigations of such men as Bernutz, Tait, W. Gill Wylie and others, characteristic cases of salpingitis were very common, and went under the name of pelvic cellulitis. W. Gill Wylie claims it was true in this country until before 1882-3, since which time we find pelvic cellulitis to be a rare disease, and very seldom existing except as a phlegmon in puerperal cases.

Many of the cases we formerly looked upon as fresh attacks of old pelvic cellulitis we now find to be local peritonitis due to salpingitis.

Salpingitis does not have its origin in the Fallopian tubes except in rare cases, but is usually the result of extension of disease from the endometrium.

W. Gill Wylie says: "It is difficult to conceive a salpingitis starting up as a primary disease independent of any disease of the uterus or ovaries. It is generally conceded that it is due in almost all cases to the extension of inflammations from the uterus to the Fallopian tubes, and that endometritis, whatever be the cause of it, is liable to result in salpingitis."

According to Wylie's ideas, which are doubtless correct, anything that will cause endometritis may, by extension of the inflammation, produce salpingitis, as gonorrhœa, sepsis after abortion and labor, syphilis, tuberculosis, pessaries (stem in particular), unclean sounds, intra-uterine injections, sponges and other kind of tents.

Salpingitis may also be caused from tubal pregnancy. Anything that obstructs drainage

from the uterus or tube may cause distension of the tubes and result in salpingitis. Salpingitis, it is claimed, accompanies some of the eruptive fevers. Direct extension of inflammation from diseases of the ovaries, as a suppurative dermoid cyst, may cause salpingitis. Pelvic hæmatocele and cancer may also produce salpingitis. Suppressed menstruation from wet feet and cold may set up catarrhal endometritis, and by the narrowing of the cervical canal, which is generally the result of uterine catarrh, the proper drainage from the uterus is prevented, when the catarrhal secretion may be forced into the Fallopian tube or tubes and cause salpingitis. As the mucous membrane lining, the tube takes on the catarrhal form of inflammations, and the secretion becomes excessive—more than is drained off through the uterine end of tube; some of it escapes at its fimbriated extremity into the peritoneum, by which the tube or tubes become closed with adhesive inflammation, when a typical salpinx will follow.

Chilling of the body from eating ices or drinking cold or iced water during menstruation may in like manner set up salpingitis.

As we have learned that salpingitis is such a common condition, it should always be looked for in pelvic inflammations, for it is, in a large majority of cases, the cause of the trouble. A diagnosis, however, is very difficult when in the acute stage. But as the salpinx becomes well developed, it can generally be easily diagnosed after the acute symptoms subside.

The acute attacks women are subjected to who have salpingitis are usually local or pelvic peritonitis caused by septic matter that escapes from the fimbriated extremity of the diseased tubes or from a rupture of the tube. Any woman, then, that is so unfortunate as to have a salpingitis is in constant danger of an attack of peritonitis from the escape of septic fluid into her peritoneum, as I have described.

Catarrhal salpingitis, when the tube is not distended, cannot be made out by the sense of touch. In fact, it is only after adhesions or occlusions of the tubes, and they are distended, that a diagnosis can be made.

The symptoms of salpingitis are frequent attacks of local peritonitis; severe pain one week or ten days before menstruation; relieved after the flow is established. There is a dull, dragging, burning pain over the seat of the tube affected. To the sense of touch, a well-defined tumor can usually be detected by bimanual examination. If it is a hydro-salpinx, the tumor will be conical shape, walls of tube thin and elastic; the local pains and acute symptoms not so severe as in pyosalpinx; when if it is a pyosalpinx, the walls will be thick and inelastic; tumor club shaped.

Women who have both tubes affected are

always sterile; when but one tube is affected and both ends of diseased tube closed, pregnancy may take place, but an abortion is very likely to follow.

To illustrate the two varieties just described, will report the following cases:

Case 1.—Mrs. Y., aged 34 years, married, good family history, enjoyed fair health, and menstruated regularly without pain until 19 years old, when, during her menstrual period, she drank freely of iced water when she was very warm while working in the harvest field. From this she took a severe chill, and had suppression of her menses, attended with pain, chills and fever. A catarrhal discharge from her uterus very soon set in. She suffered intensely from dysmenorrhœa at each period, not being entirely free from pain at any time.

She was married a few months after drinking the iced water, but lived a sterile life. Her suffering continued—sometimes worse, then again better. The pain was mostly confined to her left side, and was of a burning, throbbing nature. She would have frequent attacks of what she called “inflammation,” which were doubtless local attacks of peritonitis from salpingitis. Suffered at times from cephalalgia, which was doubtless reflex from her uterine organs. Many different physicians prescribed for and treated her with no permanent benefit. The only relief she experienced from pain was while under the influence of morphia. August 20, 1890, fifteen years from first attack, I was called to visit her at Sparta, Ohio, in consultation with the attending physician, Dr. J. F. Fox. We found her confined to bed, very nervous and weak. Upon examination, her uterus was found to be stationary in pelvis from adhesions, slightly retroflected, with marked stenosis of cervix. A well-defined tumor was located in her left side which strongly resembled a salpinx.

An operation for the removal of the diseased tube or tubes was recommended as the only means of relief, which was readily consented to. She was then put upon a course of tonic treatment and requested to exercise daily in the open air. Two months later, October 30, after a thorough preparation of patient, I opened her abdomen, assisted by Drs. J. F. Fox, E. O. Morrow, W. H. Bocher, T. H. Brannan, C. H. Goodrich and D. L. Gans, and found a large hydro-salpinx on left side, with a small hematoma of left ovary. The salpinx was adherent in the lateral side of the posterior cul-de-sac, and to the broad ligament, and was with considerable difficulty removed, on account of the adhesions. The ovary was also removed. The pedicle was tied with a silk ligature and dropped. The right ovary and tube seemed natural and were left. There being no hæmorrhage of any account from the torn adhesions, the abdomen was closed without a drainage tube, silk sutures being used.

She made a good recovery, now weighs 140 pounds, a gain of 21 pounds since before the operation, menstruates regularly and without pain.

Case 2.—Miss B., aged 20 years, unmarried, family history good. At the age of 16 years she aborted at 5 months, from which she claims to have fully recovered. Two years later she contracted gonorrhœa, from which she did not recover, but was left a physical and mental wreck from pyo salpingitis. The result doubtless of gonorrhœal infection. December 8, 1890, I was first called to visit her, when I found upon examination, a double salpinx. Both of them closely adherent to the uterus and adjacent parts. They felt firm and inelastic, and so closely united to the uterus, that they seemed to be a part of it. She suffered continued pain, worse during the menstrual period. There was a purulent looking discharge coming from her uterus.

December 12, 1890, I opened her abdomen, assisted by Drs. T. M. Johnson and J. S. Pyle, when we found my diagnosis to be correct. A double salpinx, the left one was adherent to the lower part of the pelvic floor, as well as to the uterus. And it was with great difficulty that the adhesions were broken up. The right one was higher up in the pelvis and adherent to the uterus and broad ligament. The adhesions were also with difficulty separated; they were both ligated with iron-dyed silk sutures, close to the uterus and pedicles, seared with a galvanic cautery and dropped. They were so matted together by adhesive inflammation that we could not distinguish the ovary from the tube. In fact they cannot now be separated, as you can see by the specimens. As there was but little hæmorrhage no pus escaped into the peritoneum, and the abdomen was closed without a drainage tube. Iron-dyed silk sutures were used.

Patient made a good recovery and is to-day well and hearty, weighs heavier than ever before, and is perfectly free from pain; menses regular, and unattended with pain, but they continue from seven to ten days. There is still some little discharge from her uterus.

Case 1.—The cause of the salpingitis was evidently catarrhal endometritis, which was the result of suppression of her menses from drinking the iced water. Had this catarrhal endometritis been treated early by the proper remedial means, salpingitis might have been prevented, and the poor woman saved many years of suffering and the loss of an ovary and tube.

Case 2.—The cause was a specific one; quite different from case 1, and should teach us a lesson that gonorrhœa in the female is a more serious disease than we formerly looked upon it to be. For the disease may extend from the vagina to the uterus, and from the uterus to the Fallopian tubes and the peritoneum.

45 West Tuscarawas St.

ADDRESSES.

AN ADDRESS DELIVERED AT THE OPENING OF THE SECTION OF SURGERY.

At the Annual Meeting of the British Medical Association, held in Bournemouth, July, 1891.

BY JOHN WARD COUSINS, M.B.LOND., F.R.C.S.,

Senior Surgeon to the Royal Portsmouth Hospital and Portsmouth and South Hants Eye and Ear Infirmary.

RECENT ADVANCES IN THE TREATMENT OF TUBERCULOUS DISEASES OF THE JOINTS.

Historical Notes.—During the past thirty years very remarkable development has taken place in all departments of our art, and although I think the expansion of our knowledge in connection with diseases of the joints has been less brilliant than in many other directions, still it has not been less radical as regards the system of treatment. Until the time of the late Sir Benjamin Brodie confusion and uncertainty surrounded the class of disorders, but by the labors of this distinguished surgeon many of these diseases were disentangled from each other, and the affections of the articulating apparatus, which had been grouped together under the common designation of "white swelling," were clinically separated. In the fourth edition of his work on *Diseases of the Joints*, published in the year 1836, he graphically described tuberculous disease of the bones as commencing by the deposition of a transparent material in the cancelli, and afterwards undergoing transformation into a yellow cheesy substance. He drew a correct picture of the slow progress of the inflammation, the caries of the bone, the recurrent centres of suppuration, and the final termination either in imperfect ankylosis or complete disorganization of the joint, associated too often with pulmonary disease or some other visceral affection.

Brodie and Liston investigated the morbid alterations in articular cartilage and synovial membrane. They regarded the cartilages as prone to primary alterations of structure, and they initiated the doctrine that suppuration was a rare result of their primary ulceration, and that it took place only in the advanced stages of the disease, with caries of bone and destructive changes in the synovial membrane. They regarded the presence of capillaries as an essential condition of the inflammatory process, and they labored to demonstrate the vascularity of cartilage in disease. The pathological doubts and difficulties of these eminent surgeons occupied the attention of many of their followers, and their clinical observations were marked by clearness and accuracy, but their minds were prevented from forming correct interpretations of their facts by their strange prejudices and imperfect views of the healthy and morbid processes.

Some of the problems surrounding this structure were, however, at length solved by the labors of Redfern, Goodsir, and Rainey. These observers clearly demonstrated the changes which took place in cartilage by the perverted activity of disease. They asserted that it remained entirely non-vascular, and that its disorganization was always accompanied by changes in the size and form of the corpuscles, and the softening and breaking up of the intercellular substance. During the process of repair they discovered that fibrous tissue has formed, and that into this new substance vessels were projected from the vascular system of the bone and synovial membrane, and thus the difficulties concerning the vascularity of inflamed cartilage were cleared away.

The Old Pathology of Tubercle.—The loss of substance in articular cartilage long occupied a prominent place in the pathology of joint disease, and observations on the wear and tear of this texture in the joints of men and animals were utilized in support of a mechanical theory of incipient disease. At length, however, these narrow

doctrines languished under the expanding power of broader views. The belief soon became general that joint disease could have an origin in any of the joint structures, and that most frequently the error commenced in the bone or the synovial membrane. In a large proportion of chronic affections the morbid changes were found to be the results of a peculiar inflammation, attended by the deposition of a semi-transparent exudation, which had a tendency to unhealthy suppuration, and to undergo fatty transformation. Pathologists diligently studied the scrofulous affections of bone, and for a long period of years the essential element in the process was described as a deposit of tubercle—a formation of low type which sooner or later excited destructive changes in the surrounding structures. In one case a synovitis issued in a gelatinous degeneration which ultimately extended to the bone and cartilage; in another case, the deposition of tubercle in the cancellous structure caused an expansion of the bone which insidiously progressed towards softening and caseous changes, inflammation of the fibrous capsule of the joint, and hopeless destruction by suppuration and caries.

The Scrofulous Diathesis and Tubercle.—Now, the universally accepted theory of all these changes was the unfortunate possession of a bodily or constitutional condition which was styled the strumous cachexia. This was explained as an altered direction of the normal nutrition of the system, which could make itself visible on slight provocation in any of the structures or organs of the body. Scrofula was regarded as an inherited or acquired constitutional condition, which might at any moment assume the appearance of a distinct tuberculous disease. On the other hand, tuberculosis was always manifested by a wider departure from normal nutrition, and presented new and lowly-organized formations which were deposited somewhere in the organism in the course of chronic strumous inflammation. Virchow described scrofula as a disease of the lymphatic system, and tubercle as a new product derived from the lymphatic elements of connective tissue.

Universally, then, tuberculosis was defined as in inheritance very variable in individuals; at the same time, outside influences were recognized as powerful factors in kindling the smouldering flame into activity. For many years the nature of tubercle received profound investigation, and on every hand the results of research tended to establish the time-honored theory. The microscope failed to detect in it a specific element. All the histological constituents were in turn considered the essential ingredient in the deposit. Cells and granules, epithelial elements, and cells of giant form, were searched for some characteristic quality. Some of them appeared embedded in a fine homogeneous stroma, while others were either shrivelled or drowned in particles of oil, or else buried in molecular matter. The morbid changes in bone were searched over and over again, but in the process of degeneration and caseation only negative elements were discovered. In one part the osseous structure was observed undergoing destruction, in another the osteoblasts were at work forming masses of protecting bone. With one voice the microscopists declare that they could find no specific element, and that tubercle was so definite in structure that it could be recognized by negative rather than by positive characters.

Now these were the opinions which for more than half a century were confidently taught in all the schools. Surely the experience of our day is sufficient to convince us that there is no part of our pathology which may not be transformed, and no theory which may not be pulverized by progress. These doctrines were considered orthodox for many years, and by the profound investigations of many eminent men all difficulty appeared to have passed away. Tubercle had been examined by the best observers in the civilized world; thousands of clever eyes had gazed at it with intense persistency and curiosity, and with a remarkable unanimity they pronounced

the opinion that it really contained nothing but cells.

The Modern Pathology.—In the year 1882 the whole pathology of tuberculosis underwent a great evolution by the complete demonstration of the life-history of the tubercle bacillus. The disease occurring in any tissue of an organism must now be regarded as a specific disorder, the bacilli as the direct cause of all the morbid changes, and their presence as the distinctive sign of the disease.

Now it is only by drawing a comparison between the old and the new pathology that we can really decipher the magnitude of the revolution in our conceptions. We no longer fight about the primary seat of the disease, for it is now certain that it may commence in any of the tissues of a joint. At the onset it may be synovial or osseous, and when the origin is in the latter structure it may select its surface or its substance. Strumous disease of the bones and joints is the same disease as tuberculous disease of the bones and joints; for in all these affections a specific deposit can be detected. Tubercle bacilli are never found but in this special product, and wherever the tuberculous tissue is discovered this microbe has obtained a resting-place. Their number may vary in the diseases of different structures, and also at different periods of the same disorder; still, when only a few are present they will be found by careful scrutiny.

The new pathology of tubercle is sustained by a mass of evidence derived from microscopic research, the artificial cultivation of the parasite, and experimental inoculation, so that the old notions which had long surrounded the disease have been numbered with the things of the past. The long-accepted causes, too, have been dislodged from their position, and are rightly grouped as morbid tendencies. The inheritance of constitutional peculiarities, the liability to chronic inflammations, and the susceptibility to external influences are thus regarded as essential conditions which help the microbe to establish itself within the body. Still, these factors are not less potent because the specific character of tuberculosis has been recognized. Hereditary proclivities and physical peculiarities of structure have not fallen into insignificance, but in their new position it will be possible to better estimate their potency.

Hereditary Transmission.—As regards the old doctrine of hereditary transmission, must we abandon it altogether? How is it possible for the disease to be conveyed from the parent to the embryo, unless the spores of the bacilli are themselves actually transmitted? The living particles have in themselves no penetrating power, still their vitality is certainly intensified by contact with living tissues. As a general rule, they make an entrance into the body by the mucous surfaces, and then their diffusion is secure through the ever flowing streams of blood and lymph. We know that they find their way into the bones and joints, and there appears nothing likely to prevent them getting entangled with equal ease in the placental structures. I believe, however, that there is at least some evidence in support of the assertion that the microbe can pass freely from the mother to the fœtus.¹ The great discovery of Koch may have around it many problems yet to be unraveled. It is, however, a fact of history that, by his profound research, he brought to light from the microscopic elements of tubercle a living atom which no human eye had seen before. Some have been so generous as to call it a lucky hit, but let us remember that the accident happened to a man of untiring energy and prodigious power of mental concentration, and these are qualities as essential for success in science as the full activity of the higher intellectual forces. I regard this power of mental concentration as the noblest element of genius. Do not the histories of men illustrious in science exhibit a passion amid their solitary labors? Every line of eternal truth that has been added to our knowledge, every new fact that has been brought to light from the deep secrets of the universe, every noble success in the

¹ Birch-Hirschfeld and Schmöll, Beiträge zur. path. Anat. und zur allg. Path., 1891, p. 429.

onward march of science, every triumph achieved over the mysteries of the natural world, are the offspring of unceasing devotion.

Arrest Possible in the Early Stage.—The modern pathology of tuberculosis has already exercised a salutary influence over surgical treatment and the progress of conservative surgery. Its distinct recognition of a specific and infectious disorder, in all its various manifestations, has placed the hope of arrest on a very different basis to that which it previously occupied under the old constitutional theory. During the early stages of joint disease the morbid action is often localized, and, therefore, arrest is at least possible. There can be no reason why a joint or a bone should not recover, and the tuberculous infiltration atrophy, and ultimately shrivel into a fibrous scar, just like a similar deposit in the apex of a lung. If the number of bacilli found by microscopic observation in a part are to be taken as any indication of the activity of the disease, then repeated observations are favorable to the conclusion that incipient disease in the articulating apparatus is more hopefully situated than incipient disease in the pulmonary tissue.

It is true that the early arrest of tuberculosis has long been the result aimed at by treatment. Half a century ago Brodie described the slowness of the process. The cure in the advanced stages, he said, began when the sinuses closed and the oedema of the limb subsided, but the morbid changes in the joint generally terminated in more or less ankylosis, caused by the destruction of the articulating surfaces. The diseased limb should be kept in a state of perfect quietude; not that this alone would restore the bones to a healthy condition, but it would do much to prevent the inflammation extending to other structures. He recommended constitutional treatment, residence at the seaside, nutritious diet, and exposure to fresh air.

We now restrict the term tuberculosis to those local and general changes which are directly caused by the irritation of a specific bacillus. Under favorable conditions, isolated patches of tuberculous formation may undergo atrophy, and the infiltration around them cease to extend. This arrest is the result of the timely death of the micro-parasite, for surely by its destruction alone the morbid action in the diseased tissues can be localized, and the individual delivered from the danger of a diffused tuberculosis. What, then, constitutes the grave difference between this curative process and the insidious progress of the disorder? Does it depend upon the strength of the inoculation and the number and vitality of the bacilli; or is it due to the intensity and persistency of the predisposing conditions or other factors in the causation which may be vital, or chemical, or structural peculiarities of blood and tissue? In the light of new facts, I think we must admit that the case is really dependent upon the complete destruction of the specific cause within the affected structures. At the same time, experience teaches us that arrest is possible, and that this fortunate issue may be obtained by the healthful influence of sunlight, pure air and good food upon the whole organism. I wish some philanthropic millionaire, for the sake of humanity and science, would try the experiment of submitting five hundred scrofulous children living in the slums of our large cities, and suffering from incipient joint disease, to the renovating power of good food, in combination with seaside purity and brightness, for at least eighteen months, and I am sure some of them would by these potent remedies, and the application of a simple splint, escape from more serious surgical treatment.

Value of Expectant Measures.—In the management of joint disease we must take care to select the right moment for surgical interference. It is often an anxious question to decide when expectant measures ought to be abandoned. In the early stages the diagnosis may be open to question. Sometimes the threatening symptoms may be traced to a traumatic cause. There may be nothing

in the local condition to indicate its specific character, and the general conformation and nutrition may not point to any predisposition to tuberculous inflammation. The affected joint may be swollen and occasionally painful and tender. Its outline may be altered and the normal movements impaired, and these slight indications may be marked by a persistent tendency to recurrence. In some cases the morbid action appears to have subsided, and the joint structures to have regained their healthy condition, but this favorable quiescence may be disturbed by the slightest injury, and any trivial accident may rouse again the dormant malady. Occasionally we obtain evidence of arrest many years after the favorable issue has occurred. I have seen several cases in which slight shortening of a limb has not been recognized until puberty, the period of life when the skeleton is in a condition of active development. The osseous deficiency is the result of latent mischief near the growing line, and the remnant of bygone epiphysial inflammation which happened during early life.

The Late Hugh Owen Thomas.—A few years ago strumous children laboring under chronic joint disease were kept in bed for many months, but now expectant treatment can be carried out more hopefully by combining rest and protection of the limb with fresh air and exercise. The management of incipient joint disease has fortunately undergone a silent revolution through the mechanical genius of the late Hugh Owen Thomas, of Liverpool. His surgical appliances are admirably adapted for taking off concussion, arresting friction, and imparting support and protection without pressure; at the same time they are so simple in construction that the patient can adjust them without assistance. Thomas's splints have been utilized by surgeons in all parts of the world, and the name of our old colleague will long have an honorable place in the surgical records of our times.

Tuberculin.—When, a few months since, the celebrated announcement reached us that a new remedy had been discovered which possessed the remarkable power of causing the necrosis of living tuberculous tissue, a new method of arrest appeared probable in recent cases, and material improvement in others of greater severity which would prepare them for surgical treatment. It is not my intention, however, to invade the arena of my distinguished colleague, Mr. Watson Cheyne, who has promised today to tell us the results of his elaborate investigations with tuberculin, but I feel bound to mention that although I have used the remedy in many cases of joint and bone disease without decided benefit, it will still receive from me a full and impartial trial. It is certain that it contains an agent which is capable, even in almost an infinitesimal dose, of exciting active changes in the body containing any traces of active tuberculosis. In the chemical aspects of microbial life, and in the complex bodies which are formed by the artificial cultivation of the bacilli themselves, we discern the direction from which we may anticipate future discoveries. I regard the search for a remedy amid the growth of these living particles as a splendid effort to reduce the magnitude of a world-wide pestilence, for which, up to the present moment, no really scientific treatment has ever been propounded. The great German investigator has not yet finished his work; let us patiently wait for his results, and keep ourselves free from prejudice, hoping that his daring assault upon the most deadly of diseases may ultimately be crowned with success.

Surgical Treatment of the Past.—The recognition of the local character of tuberculosis in diseases of the joints has opened up the high road to many of the recent advances in surgical treatment. Sixty years ago these disorders were described by Sir Benjamin Brodie as having their origin in the cancellous structure of the bones, or as a consequence of inflammation extending from the synovial membrane to the osseous tissue. Morbid action, he said, commenced sometimes in one and sometimes in another texture, and in the advanced stages, all the

structures of the joint became involved in the disease. At that time, however, the surgical treatment was really little else than splints and plasters, incisions and punctures, and at length amputation as a final remedy. The constitutional theory of tuberculosis blocked the road of progress.

Fergusson and Butcher.—Between the years 1830 and 1840, Syme in Scotland and Liston in London revived with energy the resection of joints for disease, an operation which had been occasionally performed by British surgeons half a century before. But it was not until Sir William Fergusson had successfully practiced it that excision became an established manipulation on all the joints, and professional prejudices were vanquished. Only a few months since, Richard Butcher, of Dublin, passed away after a long and brilliant career. He labored, too, in his day, to resuscitate the practice of excision, and devised the well-known saw especially for joint operations, and this ingenious instrument has certainly assisted the progress of conservative surgery.

Early Efforts.—Until the last few years early operations in joint disease had scarcely received any attention. In 1878, Volkmann, the inventor of the cutting spoon, performed several partial excisions in recent cases of hip-joint disease, but his results did not stimulate him to further trials. Since the year of the pathological revolution (1882) many favorable cases have been recorded, and I feel confident the practice, although still regarded by some as experimental, has already saved many limbs from graver operations.

Advantages of Early Operation.—Whenever the indications for surgical interference are clear, early operation must be attended with many advantages. The risk of delay is always in proportion to the progressive and obstinate character of the disease, and timely aid will often prevent its extension, and at the same time deliver the patient from the danger of deep infection and the development of secondary tuberculous centers. The only hope of cure must depend upon the complete removal of the diseased tissue, and the facility with which this can be accomplished rests entirely upon the extent of the local mischief. The preservation, too, of useful mobility in the joint may be anticipated when the morbid process is well localized, so that the manipulation involves only a limited excision of synovial membrane and a partial division of the fibrous capsule.

Partial Arthrectomy.—For the successful performance of a partial arthrectomy there must be clear evidence of a localized deposit. In some cases children have exhibited very little pain or lameness, but the joint has been in some part swollen, with the capsule thickened and the bones enlarged, but without any indication of softening or suppuration. By a well-directed operation near the neck of the femur or the head of the tibia, search has been made for a spot of tuberculous infiltration, with the result that a carious cavity has been found and small sequestra successfully removed. Surely these are examples of the enormous gain obtained by early operation. If the latent disease had not been detected and cut out, the issue must have been irreparable injury of the articulation in every instance, and a more serious manipulation under conditions far less favorable.

Another recommendation for early arthrectomy is the little danger that attends the operation. With ordinary surgical precaution the risk may be fairly considered trifling, even when a portion of bone has to be resected. After a full incision in the most convenient position for exploration, and carefully defining the disease, the infiltrated tissue must be excised with the scissors or cutting spoon, and the cavity thoroughly flushed with hot water. To insure rapid union, the surface should be then dried, and the wound closed with deep and superficial sutures. The limb must be kept at rest until the healing process is complete. Up to the present time a great many par-

tial arthrectomies have been performed in this country by different surgeons, but I am not prepared to state the exact proportion of their permanent successes; and it appears to me that a report of the results of early operations from many hospitals would prove at the present time a very valuable record.

Advancing Local Tuberculosis.—The articular cartilages are seldom the seat of primary disease, for as a general rule, the morbid process has its origin either in the synovial structure or the articular extremity of the bone. When the osseous tissue is the seat of a tuberculous infiltration, the evidence of its existence is often wanting until softening occurs within it, and inflammatory reaction takes place around it. As soon as these infective changes reach the synovial membrane, they extend to all the structures of the joint. Sometimes they make their way through the superficial cancelli to the outer layer of the bone, and then superficial caries and slow suppuration are the result. At another time the morbid process advances in the direction of the articular cartilage, softening and erosion of the structure follow, and then inflammatory changes which issue, unless checked by surgical treatment, in chronic abscess, caries of bone, imperfect arrest of the disease, and finally ankylosis. Now in all these forms of advancing tuberculous disease, surgery offers the only scientific method of treatment, and we can safely repeat our incisions, scoopings, scrapings and cleanings, until the disease is eradicated and a useful joint preserved.

Sudden Infection of the Joint.—But instead of a slow disorganization, the tuberculous centre may be suddenly discharged into the capsule, diffusing the infective material over the whole synovial surface, and kindling suppurative inflammation with great rapidity. A few months since I performed arthrectomy on a child for acute infection of the knee-joint. In 1889 the little patient was under my care, in the Royal Portsmouth Hospital, laboring under a small subperiosteal abscess over the head of the tibia, close to the reflection of the synovial membrane. The swelling was freely incised, and a considerable deposit of caseous material cleaned out with the spoon. The bone was roughened perilously near the articular edge, and the parents were especially warned of the danger. Soon after the child left the hospital, the swelling slowly recurred without either pain or lameness. In the month of July last she hurt her knee during a game of play. Acute pain immediately followed the accident, attended with rapid swelling of the joint and fever. Three days after she was readmitted to the hospital under my care. The knee was at once freely opened on both sides, and the inner incision was carried through the abscess cavity over the head of the tibia. The capsule contained about 3 ozs. of a turbid fluid with many flakes. The infiltrated synovial membrane was freely incised with scissors, the joint thoroughly cleansed, and the limb carefully placed on a back splint. Irrigation was continued for a week. The child was discharged quite well in January. The movements of the knee are now normal, a result due to immediate treatment and the limited injury of the synovial membrane.

Complete Arthrectomy.—Permit me now to offer a few remarks on the surgical treatment of more advanced cases, in which the morbid process is too extensive for any partial operation. In the performance of complete arthrectomy, a free division of the ligaments and capsule is necessary for the exploration of all the recesses of the articulation, and the excision of deep infiltrations of the synovial and osseous structures, so that the preservation of only a limited mobility must be anticipated. The whole of the pulpy granulation tissue must be dissected off, and the ligaments and cartilages carefully scraped. It is absolutely necessary to remove every particle of the diseased synovial membrane, and all tuberculous foci in the bones must also be cleanly cut out with the gouge. Care must be taken to prevent any remnants of the infective tissue being left behind on the raw surfaces, and

² Successful cases reported in the British Medical Journal by Messrs. Watson Cheyne, A. Barker and Charters Symonds.

the accidental reinoculation of the disease through the medium of the fresh incisions. I regard the method advocated by Mr. Arthur Barker, of flushing with hot water the seat of operation, to be the best way of carrying out these important precautions, and for the rapid performance of this part of the operation, his ingenious scoop and irrigator will be found of great practical utility. The operation of arthrectomy of the hip can be readily performed by the anterior and vertical incision and division of the neck of the femur with the saw, and then the excision of the infiltrated tissues. After a simple protective treatment for a few weeks, and the application of a Thomas' splint during convalescence, the results are often very satisfactory.

Surgical Treatment in the Advanced Stage of Hip Disease.—With reference to the old method of operating in the advanced stages of the disease, after suppuration has been proceeding for months, and sinuses have long riddled the soft parts, and when the unfortunate patient has been exhausted by a general tuberculosis, I sincerely hope it will soon be cast into the shade forever by the light of modern progress. It is my experience that these distressing cases recover more frequently by simple measures, consisting of free incision, scooping, irrigation and drainage, and that the ultimate results are more satisfactory than those which follow the practice of severe and dangerous operations.

Complete Arthrectomy of the Knee-joint.—In performing complete arthrectomy of the knee joint I consider the old horse shoe incision, and an oblique division of the ligament patellæ, better than any other method for obtaining free access to the interior of the cavity. The practice of lifting up the tuberosity of the tibia instead of division of the tendon may be found very useful in some cases. It is important to clean carefully the lateral and crucial ligaments, and to avoid damaging the cartilages and articulating surfaces. Sometimes carious bone can be removed with the gouge outside the capsule of the joint. It must always be our object to secure the complete extirpation of the diseased structures, and to preserve as far as possible the mobility of the articulation. Fortunately the limb is not shortened, and the development of the bones is scarcely impaired. The articulating surfaces are in a great measure preserved, and the operation when compared with resection of the joint is attended with less risk of life. After arthrectomy I have seen a sound and useful limb with movement to the extent of 45°, and the patient capable of standing and walking many hours every day without fatigue. So good a result can only be anticipated under favorable conditions and early surgical interference. I have received from my colleagues in different places very varying reports of their successes. Sometimes they claim firm ankylosis, but at other times their operations have issued in weak limbs and joints, tending to serious flexion and displacement. Many of them were, no doubt, too late arthrectomies, and the careful excision of the bony surfaces would have been followed by firmer and better results.

The Old Operation of Excision.—With reference to my own practice, I prefer at once complete resection in all cases marked with old sinuses and the carious remnants of old infiltrations. My method is to freely open the joint and to remove as thin a layer of bone as possible from all the articulating surfaces. The gouge is used for cleaning out any infiltrations, and then the patella is divided vertically with the saw. After cleaning every recess in the capsule, the bones are jammed together as tightly as possible, the periosteum is carefully sutured, and the wound closed, except at the extreme ends of the incision. Now, I do not presume for a moment that my results are exceptionally good, but I beg to submit to you photos of some of my patients upon whom operations were performed many years ago. I have often questioned them with reference to the inconvenience of the ankylosis, and, without exception, they have regard-

ed it with indifference. One patient volunteered the remark that the only annoyance her stiff limb caused her arose from the necessity, when sitting in company, of crossing her legs.

Conservative Surgery in the Advanced Stages of Tuberculous Disease.—I am no advocate for any attempt at conservative surgery in the advanced stages of the disease, not from the dread of deepening the general and local infection from re-inoculation through the seat of operation, but rather from the feebleness of the vital power which has been slowly undermined by prolonged suffering and suppuration. The intensity of the disease has been quickened by a chronic septic condition of the system, and it is the danger of its sudden aggravation, even with every possible precaution, which adds to the risk of surgical interference. The microorganisms of septicæmia, or their poisonous products exert a marked influence over the course of tuberculosis, for their presence reduces the resisting power of the system, and helps on the local and constitutional spread of the disease.

But it is not only septic infection in its various forms that we have to combat, but every other kind of acute disorder of the blood. Children especially are liable to be attacked with any of the infectious fevers; and these are all attended with peculiar risks. Measles, from its disturbing influence over nutrition, is prominent among the group, for its power of rekindling tuberculous inflammation.

Occasionally, however, I think that my experience has seemed to point in the opposite direction, and that an accidental blood storm has exercised a remarkable effect on the course of the malady. A young woman, who for many years had suffered from old disease of the knee, came under my care in consequence of acute inflammation of the joint, which she attributed to injury. Prior to this event she had undergone a good deal of surgical interference. Some years since I did a plastic operation for her, and in 1887 I performed abdominal section for pelvic suppuration and chronic peritonitis. A few days after her admission to the hospital her distress was so great and the constitutional disorder so acute, that I decided to amputate the leg. She was, however, I think very fortunately attacked with severe erysipelas of the head and face, and after a few weeks' dangerous illness her recovery all round was so remarkable, and the joint symptoms so much reduced, that I did an excision. The wound healed with rapidity, and she is now earning her livelihood on two legs instead of one.

Now, notwithstanding the opinion I have expressed concerning the risk of late operations, exceptions occasionally occur in practice when interference appears to be the better course. There are certainly cases of chronic tuberculous joint disease marked by secondary centres and general infection, and even aggravated by a chronic septic condition of the system, in which the vitality of the tissues and the residue of constitutional vigor appear sufficient to warrant an effort in the direction of conservative surgery.

Permit me to offer you two examples. 1. Here is the photograph of a girl taken a few months after excision of the elbow. At the time of the operation she was laboring under partially arrested hip disease with still one discharging sinus, and tuberculous deposit in many parts of the glandular system. She is now able to follow any occupation. 2. This is the likeness of a young woman, an orphan, with strong tuberculous history, upon whom I did a similar operation on a joint riddled with sinuses and surrounded with infiltrations. She had distinct physical indications of pulmonary complication, old disease of the opposite knee, and a persistently elevated temperature. She has now recovered with a useful arm, and is enjoying apparently good health. I am quite aware that these may prove only temporary successes, but it is our duty to look always on the hopeful side. I am, however, quite certain that their future prospects have been improved by surgical interference.

BY-LAW IV.—THE PUBLICATION OF PAPERS AND
REPORTS.

No report or other paper shall be entitled to publication in the
volume for the year in which it shall be presented to the Associa-
tion, unless it be placed in the hands of the Board of Trustees on or
before the first day of July. It must also be so prepared as to re-
quire no material alteration or addition at the hands of its author.

Authors of papers are required to return their proofs within two
weeks after their reception; otherwise they will be passed over and
omitted from the volume.

Every paper received by this Association and ordered to be
published, and all plates or other means of illustration, shall be
considered the exclusive property of the Association, and shall be
published and sold for the exclusive benefit of the Association.

The Board of Trustees shall have full discretionary power to
omit from the published *Transactions*, in part or in whole, any pa-
per that may be referred to it by the Association, or either of the
Sections, unless specially instructed to the contrary by vote of the
Association.

EMULSIONS.

Among the interesting and valuable papers
read before the Tenth International Medical Con-
gress at Berlin, was one by Dr. B. K. RACHFORD,
of Cincinnati, on the fat splitting properties of
the pancreatic juice. A more extended presen-
tation of the subject by the same author appear-
ed in a late number of the *Journal of Physiology*.
RACHFORD opens his paper with some remarks
on emulsions, which it is our purpose this week
to review briefly.

In 1878 GAD called attention to the fact that
when a drop of oil containing $5\frac{1}{2}$ per cent. of
fatty acid was carefully placed on a one-fourth
per cent. solution of sodium carbonate, a perfect
emulsion was immediately and spontaneously
formed. A very little more or less than $5\frac{1}{2}$ per
cent. of acid gave an incomplete emulsion. From
these facts GAD concluded that outside mechan-
ical force was not necessary to the formation of a
perfect emulsion, but that the chemical force
which was developed from the soap formation,
was itself sufficient to break the oil into the
finest globules, and that the soap formed coated
the globules and maintained the emulsion.

RACHFORD found that no amount of stirring or

shaking would produce a permanent emulsion of
either neutral or rancid olive oil and distilled
water, nor with neutral oil, and one-fourth per
cent. carbonate of sodium solution, but that
shaking would produce a good permanent emul-
sion of rancid oil and one-fourth carbonate of
sodium solution, even though the oil contained a
very large or a very small percentage of free acid.
Yet the spontaneous emulsion only forms when a
definite percentage of free fatty acid is present.

When olive oil is heated it is partly split up
into fatty acid and glycerine, and in this condi-
tion is readily emulsible, but if it be neutralized,
it is no longer emulsible, showing that the acid
is necessary for its emulsification. As RACH-
FORD suggests this fact is no doubt of import-
ance in connection with the cooking of fats, the
partial splitting up of the fat by the cooking
preparing it for its subsequent emulsification.

RACHFORD also found that if bile be present
an emulsion cannot form, although all the
conditions otherwise favorable to its formation
be present. If bile be added to an emulsion the
moment after it is formed, the emulsion rapidly
clears by creaming, but no free oil appears on the
surface. Here it seems that the soap not in
membranes is dissolved; this increases the specific
gravity and diminishes the viscosity of the liquid,
and as a result the soap-coated globules rise to
the surface as cream. If bile be added to an
emulsion some minutes after it has formed, it has
no effect in destroying the emulsion. The
stronger acids, even in very dilute solution,
rapidly destroy the emulsions, the free oil rapidly
rising to the top of the liquid.

The observations as to the influence of bile on
the formation of emulsions are particularly in-
teresting, as they show how bile regurgitated
into the stomach, could very seriously embarrass
the digestion of fats.

The formation of the spontaneous emulsion
was used by RACHFORD in a very ingenious way
to determine the action of the pancreatic juice in
fat splitting, and the effect of other digestive
agents in modifying this action. This part of
his paper we shall review next week.

THE ALVARENGA PRIZE for 1891, of the Col-
lege of Physicians of Philadelphia, has been
awarded to Dr. L. Duncan Bulkley, of New York,
for his essay on Syphilis Insontium.

THE ASSOCIATION OF AMERICAN MEDICAL COLLEGES.

The second annual session of this Association, recently held in Washington, adopted a permanent constitution and by-laws, and the interesting session was marked by harmony and enthusiasm. Colleges becoming members of the Association must demand of their students, before they receive the M.D. degree, that they have attended three full courses of medical lectures of not less than six months each, no two courses being in the same year. The entrance examination, as prepared by Drs. Osler and Millard, were adopted without change. These require that colleges becoming members of the Association, shall demand of all matriculates an entrance examination equal to the following :

1. By writing legible and correctly a composition of not less than 200 words.
2. By the translation of easy Latin prose.
3. By passing an examination in higher arithmetic or the elements of algebra.
4. By passing an examination in elementary physics.

It is provided, however, that the matriculates or graduates of recognized colleges of literature, science or the arts, or graduates of high schools of the first grade, or of normal schools directly supported by the State, be exempt from this examination. Students are allowed one year to remove a condition in Latin.

As provided at the Nashville meeting in 1890, the provisions of this examination become operative in 1892. In view of the high character of these requirements, one college withdrew from the Association, and a very few delegates that had the credentials of their college were deterred "for the present" from participating in the meeting. The colleges that at present withhold their support from the Association are of two classes: Less than half a dozen of our best institutions having a policy of extreme conservatism, or perhaps provincialism; secondly, about a dozen two-course institutions. Perhaps the colleges in the first class would not be benefitted by membership in an Association recently organized for the purpose of elevating the standard of medical education in the United States, but certainly they should give their moral support to the movement for bringing about a better system of medical education in this country. The policy

of the Association is to establish and maintain a minimum of requirements, below which no college can go and claim recognition or respectability. The Association has the enthusiastic support of the American Academy of Medicine and of the American Medical Association.

The Association should have the hearty support of all the high-grade schools. A majority of the colleges in the country are now members of the Association, and it is hoped that at the next annual session the membership will be so increased as to include every college in the United States whose teachers really desire a better system and higher grade of medical education in this country.

A MEDICO-LITERARY CURIOSITY FROM CHINA.

A somewhat unusual occurrence has been announced in the translation into Chinese of a semi official English book, by an American medical missionary, which translation has a preface written for it by the prime minister, Prince Li Hung Chang. The book is a quarto reproduction of Squire's edition of the British Pharmacopœia. The prefatory remarks by the powerful Prince are volunteered for the purpose of inducing the physicians and druggists of that country to become better informed as to the latest developments of Western methods of treatment. And the editorial writer of the *Lancet*, July 4, comments upon the singular event by saying that for nearly all that it knows of Western healing, China is indebted to the underpaid and underestimated efforts of medical missionaries. This intelligent Prince, having experienced in his own family the benefits of a missionary physician's practice, in the saving of the life of his own wife after the native doctors had given over her case as incurable, became the instrumentality for the establishment, at Tient-sin, of a hospital of sixty beds, he agreeing to pay the current expenses for a certain number of years. This institution, known as the "Viceroy's Hospital," was built at a cost of \$10,000, contributed chiefly by the Chinese themselves. The same issue of the *Lancet* has an item with regard to the amount of surgical work sometimes performed at these missionary hospitals, stating that the brothers Doctors Neve, of Srinagar, Kashmir, did, in the year 1890, about 3,000 operations, of which 759 were capital or severe.

LIFE-SHORTENING OCCUPATIONS.

One of the curious features of modern life is the extent to which the most hazardous trades are overrun by applicants for work. The electric light companies never find any difficulty in obtaining all the linemen they need, notwithstanding the fact that the dangers of that kind of business have been demonstrated times without number. The men who work in factories where wall-paper is made frequently joke one another over the tradition that a man's life, in this trade, is shortened ten years. A similar belief is prevalent in factories where leather papers are made, and among men who have to handle them, and whose lungs are said to become impeded by inhaling the dust arising from those papers. In certain other factories where brass ornaments and fittings are made, the air is laden with very fine brazen particles which are, when inhaled, especially irritating to the lungs. But one of the most singular advertised calls for employés that ever was printed, appeared recently in a Connecticut newspaper, signed by a firm engaged in the business of building towers. It called for applicants only among those who are young, strong and courageous, and closed by saying, "We warn all seekers for this job that it is of the most dangerous nature, and that few men continue in it more than a few years. In fact, it is almost certain death to the workman who follows this occupation." This frankness on the part of the advertiser was commendable, and probably deterred no one who seriously canvassed the taking up of that occupation. There was presumably no dearth of candidates for this life-shortening, since the advertisement was withdrawn after a few days' publication.

IOWA STATE BOARD OF HEALTH.

The Secretary of this Board has made an official deliverance to the effect that habitual inebriety on the part of a medical practitioner shall be regarded as "palpable evidence of incapacity," and should render the drunken delinquent liable to the revocation of his certificate entitling him to practice in the State of Iowa.

AMMONIUM BROMHYDRATE vapors are recommended in lieu of ammonium chloride as an inhalant in some forms of bronchitis and nasopharyngeal catarrh.

DOMESTIC CORRESPONDENCE.

Antipyrin in Whooping-Cough.

Editor Jour. Amer. Med. Ass'n:—Though antipyrin has been recommended now for some time in the treatment of pertussis, I am surprised to find still a considerable amount of indifference in regard to its employment, either through ignorance of its beneficial effects or fear of its dangers. Like Sonnenberger, I am almost inclined to regard antipyrin as a specific in this affection, though in using the term *specific*, I am aware that the action of the drug is exercised not so much upon the disease itself as upon the nervous system, in quieting the reflex spasmodic cough. It seems to me that the conclusions drawn by Ssemitschenko, after a close and careful experimentation, oblige us to consider the real cause of pertussis a bacillus, probably the bacillus of Afanassjew. This bacillus is specific. It is found in the sputum about the fourth day, or even earlier. It multiplies in the tissues of the body, and increases with the increase in the severity of the disease. With complications like catarrhal pneumonia it is discovered in the sputum in large numbers, and it is a long-recognized fact that this form of pneumonia differs from all the ordinary forms.

Rational medicine would, therefore, seem to indicate the use of antiseptic sprays and inhalations. Carbolic acid has long been thus employed, and I am still a strong advocate of it. But notwithstanding the use of the spray and the usual internal medication, the reflex irritability of the nervous system becomes so increased that the so-called spasmodic stage of the disease is the most distressing to the patient and his attendants. It is also the most dangerous, on account of the asphyxia by which the spasms are accompanied, and the troublesome pulmonary complications which are so prone to occur. It is in this stage, then, that sedatives are demanded above all other forms of medicine, and I know of none to equal antipyrin in allaying the reflex excitability of the nervous system. Of course I continue the carbolic spray through this as well as the earlier and later stages of the disease; but my attention is almost wholly given, at this time, to the relief of the spasmodic coughs which so quickly exhaust the patient's strength, destroy his desire for food, and prevent the necessary sleep at night. Sonnenberger declares that the best results are obtained the sooner the antipyrin is given in the disease; my experience leads me to believe that this early administration of the drug is not necessary in all cases. It is a powerful remedy, and must be employed in full doses to secure the desired effect, therefore I usually reserve it for the paroxysmal stage, and commence giving it only when the child begins to whoop.

During a recent epidemic of this disease in one of our suburban towns, I gave the antipyrin in three cases, aged respectively five, eight and ten years. All of the children, particularly the youngest, possessed a decidedly neurotic type of constitution. The disease was marked, characteristically severe, and passed regularly through the three typical stages. I began with the carbolic spray from the very outset of the trouble, combining with it

the internal administration of some of the older remedies of the sedative and expectorant class. In the second stage the paroxysms became so violent at night, particularly in the case of the youngest child, as to cause both myself and the attendants considerable anxiety. Frequently the spasms would be so severe as to completely arrest respiration for many seconds, and the ensuing cyanosis would be as pronounced as one ever sees it in this disease. With a feeling of complete exhaustion, the little patient would then throw herself on the bed, the eyes watering and the face highly flushed. Finally she would sink into a profound sleep, to be abruptly awakened soon again by a repetition of the same violent paroxysm. This was the state of affairs when I ordered for each of the children two grains of antipyrin three times a day, with an extra dose at bedtime. I furthermore directed the attendant to give the powder more frequently if this did not cause any decided amelioration in the frequency and severity of the paroxysms. To my gratification there was a change almost immediately. The coughing spells diminished to only two or three in the twenty-four hours; the child secured the needed rest at night, and the appetite and general health began to revive. Rarely was it necessary to give the powder oftener than as directed at first. During its administration I have never witnessed the slightest untoward symptoms. Sonnenberger gives it three times a day, in doses of about as many centigrammes (one-sixth of a grain) as the child is months old, or as many decigrammes (one and one-half grains) as it is years of age. While I do not think it would be safe to give the same dosage to all children according to such a fixed rule, I find that generally they bear larger amounts comparatively of the drug than adults. I would urge its careful administration at all times, beginning with the minimum dose, and increasing the same until the desired effect is obtained. Its beneficial action is undoubtedly due to the power which it possesses of depressing the reflex excitability of the nervous centers, and it should be administered, therefore, with a view to the effect rather than the mere size of the dose. I consider the carboic acid spray, with the internal administration of antipyrin *pro re nata*, the most satisfactory method yet advanced for the treatment of whooping cough.

Premature Rupture of Membranes not Followed by Miscarriage.

To the Editor Jour. Am. Med. Assoc'n:—I remember reading in THE JOURNAL, some months ago of two cases in which premature rupture of the membranes was not followed by the usual result—a miscarriage. A case having come under my observation recently, I will record it, not for the purpose of going into a discussion of the subject, but as a mere statement of facts.

Mrs. R., multipara. White, 28 years of age; pregnant for fourth time; had, when about five and one-half months advanced, a severe fall—followed by an unmistakable flow of quite a quantity of the amniotic fluid. As no pain followed, the treatment was simply rest in

bed for twenty-four hours; after this she felt so well that she resumed her household duties. Pregnancy went to full term and a normal labor terminated in the birth of a strong healthy ten pound child.

Such cases are, I believe, sufficiently uncommon to be of interest to the general practitioner, showing as they do that labor is not the absolutely essential result of rupture of the membranes. Why one woman should have this result and another not is hard to determine. Probably the location of the opening into the amniotic sac is one of the important factors. Another, as I look at it, is the marked difference in the irritability of the uterus in different women. Certain it is some women miscarry on the slightest irritation to any portion of the uterus, while others will go to full term through falls, shakes, railroad accidents—even through the vigorous attempts at abortion performed either by themselves or by some of the human monsters that infest our cities and large towns.

The only treatment that such a case would call for would be rest—perfect rest in bed—and opium in some form to control the muscular action of the uterus.

Pains coming on in spite of this would indicate miscarriage, and then of course the treatment would vary according to the circumstances of the individual case.

Prof. Obst., Col. Phys. and Sur., Boston, Mass.

A Successful Method of Removing Foreign Bodies from the Alimentary Canal.

Editor Jour. Amer. Med. Ass'n:—During the past few months, the writer has been consulted on several occasions by anxious parents whose children have swallowed bits of coin. In each case I have invariably given the parents similar advice. Place the patient upon an exclusive potato diet. The potatoes may be either mashed, baked or boiled.

This method in my hands has been thus far successful. This treatment is adopted, to the exclusion of all others, in the Vienna General Hospital, as I ascertained when visiting that hospital about a year ago. This manner of dealing with patients who have swallowed foreign bodies cannot be too generally known.

BOOK REVIEWS.

LECTURES ON TUMORS, FROM A CLINICAL STAND-POINT. By JOHN B. HAMILTON, M.D., LL.D. 12mo, cloth, pp. 138. Detroit: George S. Davis. 1891.

This book, which is intended for the use of students, is the substance of twelve unpublished lectures on tumors, delivered at the Georgetown University in Washington. There are many books descriptive of the pathology of tumors, but few combine the clinical observations necessary to an

understanding of their treatment. This, the little book undertakes to do, and each in the long list of tumors mentioned in the accepted nomenclature, are spoken of briefly, and the symptomatology, diagnosis and treatment given. The book is said by our author to be really the introduction to a larger work on tumors of the regions which, in connection with other well-known writers, he has in preparation. In regard to nomenclature and classification, he adheres to that of the Royal College of Physicians and Surgeons, stating that while that is not at present the ideal classification, yet we must have some standard, and moreover, at the last revision the American Medical Association was consulted, and through the Army Medical Department's representative, the National Board of Health, then in existence, and Dr. C. F. Folsom, of the Harvard Medical College, were also advised with. The day has passed when every man should have his own nomenclature manufactured by himself, and the interest of science demands uniformity in medical and surgical nomenclature, even at some sacrifice. The nomenclature recognized in the book was last revised in 1885 and the author truly says, there is considerable material now ready for the next committee of revision. The student will find here a complete elementary treatise on this obscure subject. As there is a field for the work, there is little doubt of its extensive sale.

PRACTICAL INTESTINAL SURGERY. BY FRED B. ROBINSON, B.S., M.D. 12mo. paper, pp. 166. Detroit: George S. Davis. 1891.

The best part of this book, is the dedication, for it is dedicated to Prof. Nicholas Senn.

The author is evidently a much better practitioner than a writer, for the book is painfully filled with ill chosen metaphor, faulty construction and worse logic, while the practical directions for abdominal work are fairly good.

We will make some quotations to justify this sweeping condemnation of the style of the author, if indeed he may be said to have any.

Writing of the alimentary canal, our author thus discourses, on page 5:

"The strong muscular knots in the alimentary tract, though weak from the standpoint of disease, are subject to dilatation and contraction periodically. Their vascular supply is thus fluctuating, and subject to a maximum and minimum blood supply. At such points disease is apt to arise, just as it does in the changeable genital organs and breasts of women. Considerable muscular rings are found heaped together at the pylorus, cœcum and anus. In such periodically active tissue cancer delights to ensconce its wandering cells. The pylorus may be viewed as man's first physiological anus, the ileo-colic valve as his second, and the end of the rectum as his third but mechanical anus."

And again, on page 9: "I have found the cœcum in puppies at the end of the transverse colon; it had not yet descended, nor formed scarcely any descending colon." This is certainly an unusual situation in which to find a puppy, but we have no disposition to dispute our author's statement of facts.

On page 11, our author thus commiserates the uterus.

"Observe the poor vertical uterus around which woman is built, standing, doubtfully, capering on its giddy end, with its heavy responsibility balanced upward. Notice how it careers through a variety of naughty courses, of floods and drought, study the arrogant and defiant positions it assumes on account of man getting on his feet."

No other than the one who wrote the foregoing curiosity could have evolved the following sentence, which may be found on page 26:

"Without specifying names, I have observed death throughout abdominal literature for the past ten years in considerable numbers."

The reader will doubtless be greatly edified if he should try to analyze the sentence just quoted.

There is some good in the book, but it is generally couched in such bad form as to be of little value. We had rather praise than censure, but our duty as reviewer, and as well the true interest of American medical literature, require that such crude book-writing as is shown here, should be held up to view, that persons inclined to authorship, may refrain from encumbering our shelves with such trash, and unless our author rewrites his book, he will have another "death in abdominal literature" to "observe," quite near home.

A CLINICAL TEXT-BOOK OF MEDICAL DIAGNOSIS, for physicians and students, based on the most recent methods of examination, by OSWALD VIERORDT, M.D., Professor of Medicine at the University of Heidelberg. Authorized translation from the second improved and enlarged edition, with additions by Francis H. Stewart, A.M., M.D., of Brooklyn, with one hundred and seventy-eight illustrations. Philadelphia: W. B. Saunders.

This first English translation of so excellent a work finds itself a welcome arrival. The original found fewer readers in this country than it should have had, for reasons alike obvious and to be regretted. The translator has, however, brought its benefits within the reach of many who will appreciate his book, as well as the authors, and will deem as of secondary importance the rather numerous errata, which detract from the pleasure of the reader.

The division of the work into three parts—consisting of eight chapters and an appendix, is a convenient one.

Part I, embracing chapters one and two, is devoted to the general preliminary examination, systematically conducted and to be commended. This is supplemented by the translator in a note upon keeping records of cases, and a form for recording the results of a medical examination.

Part II, consisting of chapter three, is devoted to critical general examination of the individual patient. It is methodical and thorough, and like part one will be found to be specially serviceable to young physicians, though not without interest or usefulness to all.

Part III embraces chapters four, five, six, seven and eight. Under chapter four, examination of the respiratory apparatus is conducted in a very thorough manner.

Under chapter five, examination of the circulatory apparatus, is so subdivided and followed in detail as not only to be useful but to sustain interest in conducting the work of the examination.

Chapter six deals with the complication of digestion, examination of the digestive apparatus, —and is conducted in such manner as must result in convincing us of how much, and how little, we know definitely and reliably of the chemistry and physiology of digestion—salivary, gastric and intestinal—however well convinced we may be of the evils incident to its defective work, and the difficulty, as well as the importance, of remedying it. Chapter seven is devoted to examination of the nervous system. This is conducted in accordance with the scientific methods of the most advanced thought in the present state of neurology, and in following them, whilst advising what can be accomplished in elucidating many of the mysteries of the nervous system, one is forcibly impressed with what evidently yet remains unknown on this subject.

The appendix embraces some matters of general interest, especially what relates to bacteria, which come under consideration in the diagnosis of internal diseases.

The numerous illustrations throughout the work are generally above the average. Some of them are more than ordinarily successful delineations, and there are some good specimens of staining of bacteria. The index is full and satisfactory. The mechanical work throughout the book is good.

In all respects it is a desirable addition to a physician's library.

MANUAL OF CLINICAL DIAGNOSIS. By ALBERT ABRAMS, M.D. San Francisco: The Bancroft Company.

The author says in the preface of this small work that he makes no special claim to originality, that he has only "gathered a posie of other men's flowers, and nothing but the thread that binds them is mine own." While the writer thus

modestly sets forth his effort, we must remind him that a good text-book needs nothing original. We do not go to our school-books for critical discussions of mooted points, or for the detailed description of isolated experiments. A text-book should accurately represent the best and most approved opinion of the most advanced scholars in the particular branch of which it treats. It should be well arranged, with a good index, expressed in concise language, and free from controversial matter. An examination of the volume upon these lines shows that the writer has produced a compact and useful manual. If we would pass any criticism upon this book, it must be upon the score of what is generally a "good fault" in a text-book. The writer, in his efforts to be brief and concise, has to some extent sacrificed smoothness of diction; still, this is so much better than verbosity, that we freely forgive him.

MISCELLANY.

TRI-STATE MEDICAL ASSOCIATION.—The third annual meeting of the Tri State Medical Association will convene in Turner Hall, Chattanooga, Tenn., Tuesday, October 27, 1891, and continue in session three days. Indications are that it will be one of the largest medical meetings ever held in the South. Representative physicians from all sections will be present.

All who desire to read papers should send title to the Secretary of the Association before September 1. In due time a circular will be issued, giving a complete list of all papers and names of exhibitors who apply for space before October 1.

President—Robert Battey, M.D., Rome, Ga.; Secretary—Frank Trester Smith, M. D., Chattanooga, Tenn.; Secretary of Executive Committee—W. L. Gahagan, Chattanooga, Tenn., P. O. Box 542.

MISSOURI VALLEY MEDICAL SOCIETY.—The fourth annual meeting of the Medical Society of the Missouri Valley will be held at Council Bluffs, Ia., September 17 and 18. The Society has a membership of over 300. None but men of known professional standing are admitted as members. The membership extends along the Missouri Valley from Yankton, S. Dak., to St. Louis, Mo. Physicians residing in South Dakota, Nebraska, Iowa, Kansas, and Missouri, constitute the membership.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from August 1, 1891, to August 7, 1891.

First Lieut. Alfred D. Bradley, Asst. Surgeon U. S. A., granted leave of absence for thirty days.
Asst. Surgeon William L. Kneedler, U. S. A., leave of absence granted is extended one month.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending August 8, 1891.

Surgeon R. A. Marmion, detached from Navy Yard, Norfolk, and to the Navy Yard, Boston.

Surgeon G. F. Winslow, detached from Marine Rendezvous, Boston, and to the Navy Yard, Norfolk, Va.

Surgeon J. B. Parker, detached from Navy Yard, Boston, and placed on waiting orders.

Asst. Surgeon F. G. Braithwaite, ordered to receiving ship "Wabash," at Navy Yard, Boston.

Asst. Surgeon J. B. Uric, detached from receiving ship "Wabash," and to the Marine Rendezvous, Boston.

P. A. Surgeon F. J. B. Cordeiro, detached from Naval Hospital, Chelsea, Mass., and granted two months' leave of absence.

P. A. Surgeon G. McC. Pickerell, from hospital, New York, to hospital, Chelsea.

ORIGINAL ARTICLES.

THE CORONER SYSTEM IN THE UNITED STATES.

Read in the Section of State Medicine, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY HENRY O. MARCY, M.D.,
OF BOSTON, MASS.

I am aware that the great body of the medical profession have regarded the coroner and his duties as a subject bearing only an indirect relation to the practice of medicine. It was not until 1877, when the coroner laws were pretty thoroughly investigated in Massachusetts, that I believed they demanded revision.

The investigation of the law as practiced in Massachusetts showed clearly that it was not adapted to the best ends of justice; that the coroner, no matter how skilled in any branch of special training, could, under the law, scarcely be expected to discharge his duties in a satisfactory manner. In other words, that the primal fault lay, not so much in the functionary as in the class of duties he was expected to fulfill. The analysis of these duties showed that the same person was expected to be competent as a medical expert, to serve as an administrator of the law, as a judge to hear evidence, to decide upon its admissibility, he being also a witness in the case. Upon his own authority, or assisted by a physician, he was first to determine in a case under investigation if death had occurred by natural means or by violence; that is, by the evil intent of another. It having been decided that further investigation was necessary, a jury was summoned, and testimony was taken, usually in open session. To this he added his own testimony.

From this brief review it will be clearly observed that the office demanded two entirely distinct classes of functions to be discharged by one and the same person. These duties were both legal and scientific, and each in turn might involve questions of the greatest magnitude, often requiring the highest skill and experience in two great branches of learning. A further investigation showed that in matter of fact the office

was generally regarded as political, and that the appointees were more commonly men versed neither in law or medicine, and, as a consequence, were necessarily unfitted for the proper discharge of either of the main subdivisions of their duties. This was brought so clearly to the notice of the proper authorities that the manifest unfitness of the law for the complex requirements of modern life was plainly apparent, and Massachusetts abolished her entire system of coroner laws, and established in their place provision for medical examinations and inquest in cases of death and violence. This reformation was accomplished under the leadership of Mr. Theodore H. Tynedale, a member of the Boston bar, with the active cooperation of several distinguished members of our own profession, aided by the State Medical Society, and the law which is here given in full was adopted by the Legislature of Massachusetts in May, 1877:

AN ACT to Abolish the Office of Coroner, and to Provide for Medical Examinations and Inquest in Cases of Death by Violence.

Be it enacted by the Senate and House of Representatives in General Court assembled, and by the authority of the same as follows:

SECTION 1. The offices of coroner and special coroner are hereby abolished.

SEC. 2. The Governor shall nominate, and by and with advice and consent of the council shall appoint, in the county of Suffolk, not exceeding two, and in each county not exceeding the number to be designated by the county commissioners as hereinafter provided, able and discreet men, learned in the science of medicine, to be medical examiners; and every such nomination shall be made at least seven days prior to such appointment.

SEC. 3. In the county of Suffolk, each medical examiner shall receive in full for all services performed by him an annual salary of three thousand dollars, to be paid quarterly from the treasury of said county; and in other counties they shall receive for a view without an autopsy, four dollars; for a view and autopsy, thirty dollars, and travel at the rate of five cents per mile to and from the place of the view.

SEC. 4. Medical examiners shall hold their offices for the term of seven years from the time of appointment, but shall be liable to removal from office at any time by the Governor and council for cause shown.

SEC. 5. Each medical examiner, before entering upon the duties of his office, shall be sworn and give bond, with sureties, in the sum of five hundred dollars, to the treasurer of the county, conditioned for the faithful performance of the duties of his office. If a medical examiner neglects or refuses to give bond as herein required, for the period of thirty days after his appointment, the

same shall be void, and another shall be made instead thereof.

SEC. 6. The county commissioners in each county shall, as soon as may be after the passage of this act, divide their several counties into suitable districts for the appointment of one medical examiner in each district under this act; and when such division is made, shall at once certify their action to the secretary of the Commonwealth, who shall lay such certificate before the Governor and council. But nothing herein shall prevent any medical examiner from acting as such in any part of his county.

SEC. 7. Medical examiners shall make examinations as hereinafter provided, upon the view of the dead bodies of such persons only as are supposed to have come to their death by violence.

SEC. 8. Whenever a medical examiner has notice that there has been found, or is lying within his county, the dead body of a person who is supposed to have come to his death by violence, he shall forthwith repair to the place where such body lies and take charge of the same; and if, on view thereof, and personal inquiry into the cause and manner of the death, he deems a further examination necessary, he shall, upon being thereto authorized in writing by the district attorney, mayor, or selectmen of the district, city or town where such body lies, in the presence of two or more discreet persons, whose attendance he may compel by subpoena, if necessary, make an autopsy, and then and there carefully reduce or cause to be reduced to writing every fact and circumstance tending to show the condition of the body, and the cause and manner of death, together with the names and addresses of said witnesses, which record he shall subscribe. Before making such autopsy, he shall call the attention of said witnesses to the position and appearance of the body.

SEC. 9. If, upon such view, personal inquiry or autopsy, he shall be of opinion that the death was caused by violence, he shall at once notify the district attorney and a justice of the district, police or municipal court for the district or city in which the body lies, or a trial justice, and shall file a duly attested copy of the record of his autopsy in such court, or with such justice, and a like copy with such district attorney; and shall in all cases certify to the clerk or registrar having the custody of the records of births, marriages and deaths in the city or town in which the person deceased came to his death, the name and residence of the person deceased, if known, or a description of his person as full as may be for identification, when the name and residence cannot be ascertained, together with the cause and manner in and by which the person deceased came to his death.

SEC. 10. The court or trial justice shall thereupon hold an inquest, which may be private, in which case any or all persons other than those required to be present by the provisions of this chapter may be excluded from the place where the same is held; and said court or trial justice may also direct the witnesses to be kept separate, so that they cannot converse with each other until they have been examined. The district attorney, or some person designated by him, may attend the inquest, and may examine all witnesses. An inquest shall be held in all cases of death by accident upon any railroad, and the district attorney or the attorney-general may direct an inquest to be held in the case of any other casualty from which the death of any person results, if, in his opinion, such inquest is necessary or expedient.

SEC. 11. The justice or district attorney may issue subpoenas for witnesses, returnable before such court or trial justice. The persons served with such process shall be allowed the same fees, and their attendance may be enforced in the same manner, and they shall be subject to the same penalties as if served with a subpoena in behalf of the Commonwealth in a criminal prosecution pending in said court or before said trial justice.

SEC. 12. The presiding justice or trial justice shall,

after hearing the testimony, draw up and sign a report in which he shall find and certify when, where, and by what means the person deceased came to his death, his name, if known, and all material circumstances attending his death; and if it appears that his death resulted wholly or in part from the unlawful act of any other person, he shall further state, if known to him, the name of such person, and of any person whose unlawful act contributed to such death, which report he shall file with the records of the superior court in the county wherein the inquest is held.

SEC. 13. If the justice finds that murder, manslaughter, or an assault has been committed, he may bind over, as in criminal prosecutions, such witnesses as he deems necessary, or as the district attorney may designate, to appear and testify at the court in which an indictment for such offense may be found or presented.

SEC. 14. If a person charged by the report with the commission of any offence is not in custody, the justice shall forthwith issue process for his apprehension, and such process shall be made returnable before any court or magistrate having jurisdiction in the premises, who shall proceed therein in the manner required by law. But nothing herein shall prevent any justice from issuing such process before the finding of such report if it be otherwise lawful to issue the same.

SEC. 15. If the medical examiner reports that the death was not caused by violence, and the district attorney or the attorney-general shall be of a contrary opinion, either the district attorney or the attorney-general may direct an inquest to be held in accordance with the provisions of this act, notwithstanding the report, at which inquest he, or some person designated by him, shall be present and examine all the witnesses.

SEC. 16. The medical examiner may, if he deems it necessary, call a chemist to aid in the examination of the body, or of substances supposed to have caused or contributed to the death, and such chemist shall be entitled to such compensation for his services as the medical examiner certifies to be just and reasonable, the same being audited and allowed in the manner herein provided. The clerk or amanuensis, if any, employed to reduce to writing the results of the medical examination or autopsy shall be allowed for his services two dollars per day.

SEC. 17. When a medical examiner views or makes an examination of the dead body of a stranger, he shall cause the body to be decently buried; and if he certifies that he has made careful inquiry, and that to the best of his knowledge and belief the person found dead is a stranger, having no settlement in any city or town of this Commonwealth, his fees with the actual expenses of burial shall be paid from the treasury of the Commonwealth. In all other cases the expenses shall be paid by the city or town, and all other expenses by the county wherein the body is found.

SEC. 18. When services are rendered in bringing to land the dead body of a person found in any of the harbors, rivers, or waters of the Commonwealth, the medical examiner may allow such compensation for said services as he deems reasonable, but this provision shall not entitle any person to compensation for services rendered in searching for such dead body.

SEC. 19. In all cases arising under the provisions of this act, the medical examiner shall take charge of any money or other personal property of the deceased, found upon or near the body, and deliver the same to the person or persons entitled to its custody or possession; but if not claimed by such person within sixty days, then to a public administrator, to be administered upon according to law.

SEC. 20. Any medical examiner who shall fraudulently neglect or refuse to deliver such property to such person within three days after due demand upon him therefor, shall be punished by imprisonment in the jail or house of correction not exceeding two years, or by fine not exceeding five hundred dollars.

SEC. 21. The medical examiner shall return an account of the expenses of each view or autopsy, including his fees, to the county commissioners having jurisdiction over the place where the examination or view is held, or in the county of Suffolk to the auditor of the city of Boston, and shall annex thereto the written authority under which the autopsy was made. Such commissioners or auditor shall audit such accounts, and certify to the treasurer of the Commonwealth, or the treasurer of the county, as the case may be, what items therein are deemed just and reasonable, which shall be paid by said treasurer to the person entitled to receive the same.

SEC. 22. Whenever any sheriff is a party to a suit or proceeding, or otherwise disqualified to act therein, the sheriff or a deputy sheriff of any adjoining county may serve and execute all writs and precepts, and perform all duties of such sheriff which he is disqualified to perform, and may serve and execute all such writs and precepts wherein any county, town, parish, religious society, or school district is a party or interested, notwithstanding he is at the time a member of such corporation.

SEC. 23. Whenever a vacancy occurs in the office of sheriff of any county, the senior deputy-sheriff in service shall perform all the duties required by law to be performed by the sheriff, until the office of sheriff is filled in the manner required by law, giving bond as now required by law of sheriffs. And in case of such vacancy, the deputies of the sheriff vacating the office shall continue to have and exercise the power of deputy sheriffs until said office is filled as aforesaid.

SEC. 24. Sections seventy-five, seventy-six and seventy-seven of chapter seventeen, and section one hundred of chapter sixty-three, and section eighteen of chapter one hundred and sixty-three of the General Statutes are hereby amended by substituting for the word "coroner," wherever the same occurs, the words "medical examiner," and for the word "coroners" the words "medical examiners." The second clause of section fifty-two, and sections seventy-four, seventy-eight, seventy-nine and eighty of chapter seventeen of the General Statutes, chapter one hundred and seventy-five of the General Statutes, chapter one hundred and thirteen of the acts of year eighteen hundred and sixty-one, chapter one hundred and seventy-two of the acts of the year eighteen hundred and sixty-two, chapter twenty-eight of the acts of the year eighteen hundred and sixty-four, chapter two hundred and forty-one of the acts of the year eighteen hundred and seventy-one, and chapter one hundred and fifteen of the acts of the year eighteen hundred and seventy-six, and all other acts and parts of acts inconsistent herewith are hereby repealed.

SEC. 25. For the purposes of the appointment and qualification of medical examiners and the action of the county commissioners herein provided for, this act shall take effect upon its passage, and it shall take full effect on the first day of July next.

We shall have occasion to revert to the experience of Massachusetts during the last thirteen years to show the advantages in the working of the new law. Suffice it to state in passing, that the radical changes made in this Act are: first, the doing away entirely with the office of coroner; second, the abandonment of examination by a jury on what is necessarily a preliminary trial; third, the adoption of a new plan by which a specially trained medical expert makes a scientific investigation, and properly qualified legal officials conduct the legal inquiry, preliminary to the final trial after indictment of the accused parties.

In 1881, Dr. John G. Lee, of Philadelphia,

published a book entitled "Hand-book for Coroners," containing a digest of all the coroner laws in the United States. This valuable work consists of the selection, collation and arrangement of such material as the author could command, and is offered especially "as a guide for the instruction of newly elected coroners, or as a convenient hand-book for occasional and rapid reference." It does not appear to the author that any especial criticism should be made upon the laws as collated, or that there is an imperative need of a radical revision of the same. He recognizes, however, that there is often a difficulty of proper adjustment of the relation which the coroner holds to the prosecuting attorney and the other departments of justice, and concludes by saying: "If the coroner will administer his office fearlessly and according to the laws of his state, we feel sure that the clamor which periodically demands the abolition of the coroner and his functions will be heard no more."

However, the impartial critic who studies at all carefully the coroner laws as they exist in the several states would seem to require no better evidence of the need of their revision than therein contained, and as if in emphasis of this conclusion, the author adds a considerable number of pages of anecdotes full of grim humor which would be high comedy were it not for the seriousness of the subject.

In 1887 a committee was appointed by the American Medical Association, of which I was chairman, to examine into and report upon the coroner system of the United States. The first report of this committee was made at the May meeting, in 1888, supplemented by a report at the annual meetings of 1889 and 1890. At the last meeting a resolution was adopted in the general session calling the attention of the various State and district societies to this subject, requesting the members of the Association to personally investigate, and as far as possible to correct the evils inherent in the present system.

I desire by this paper to enlist the interest of the profession generally in this subject, as one eminently suitable for their investigation, and I sincerely trust that the influence of this learned body may be exercised in behalf of a much needed reform. It had been my purpose to examine in detail the laws in effect in each of the several States and Territories, and to this end I entered into correspondence with the secretaries of the various boards of health, and other prominent officials, and I have, as the result therefrom, collected a large amount of valuable material. However, the limit of this paper prevents an analysis in detail. The essential principles of the coroner laws (except in Massachusetts, Connecticut and Rhode Island) are very similar in all the States, and it is a source of absolute wonder how such an absurd and valueless office for

the detection of crime should have continued through all these years.

These laws owe their origin very naturally to the laws of England, and were first adopted in the early colonial days. The conservatism of English thought is nowhere better exemplified than in the history of her legal enactments. The primary medico-legal inquiry in cases of death by violence has been conducted in England by the coroner's inquest for the last thousand years, and has not been essentially changed for several centuries. According to Sir Thomas Smith, who wrote in 1583, the name of the office originated from the word "Crown," or "Coromator," because "the death of every subject by violence is accounted to touch the Crowne, and to be a detriment to it; in other words, the coroner was a representative of the Crown." The system of trial by jury has ever been very dear to the English heart, and this, in the earlier days of English history, when society was less complex than at present, was very properly associated with the duties of the coroner system. Then both pathology and chemistry were in their infancy, and the combined judgment of the average citizen represented the highest verdict of public opinion.

In the early part of the present century, Mr. Thomas Wakeley, the able editor of the London *Lancet*, pointed out the inefficiency of the coroner laws as practiced in England, and demanded that the office of coroner should be filled by a competent medical man, since which time the coroner in England has usually been selected from among the better class of medical practitioners.

At the present time, in nearly all the States of the Union, the coroner's office is considered one of political preferment, and as such, is subject to party politics, holding the office not seldom as a subsidy for supposed services rendered, rather than because of fitness to discharge duties of so great importance to the State.

In the progress of legal learning, as well as in medical science, these two great branches of special knowledge have outgrown their former status, and to be well versed in both is beyond the training and education of the present generation.

The object of a medico-legal inquiry is manifestly the detection of crime, and the evidence sought is the direct cause of death and the identity of the individuals committing the crime. To ascertain the cause of death, it often requires the highest qualification of a pathological expert. The post-mortem examination must often be made in a thorough and skillful manner, and must frequently be supplemented by a careful and exhaustive chemical research. To this portion of the subject an especially trained medical expert limits his inquiry. Here, in the large majority of cases requiring investigation, the examination should end, since by it, it is clearly determined that death has been due to natural

causes, and that the case does not come within the limit of criminal investigation. In such cases, at least, it is a useless and unnecessary expense to summon jurymen, and too often calls the attention of the public through the press to a subject keenly painful to all parties involved.

If death has not occurred from natural causes, the question then arises, has a crime been committed? In all doubtful cases, the evidence of this is largely determined by a careful, competent and thorough medical examination. When this has been fairly established, the further investigation of the relation of "the party or parties to the act" becomes a purely legal one, and here, singularly, the evidence, as usually rendered by the verdict of a coroner's jury, is generally considered of little value. In an able article¹ by Mr. Clark Bell, of New York, entitled "The Coroner's Office; Should it be Abolished?" he writes: "There can probably be no more startling evidence of the utter uselessness of a coroner's jury than the statement of this fact, that whatever may be the verdict in a given case, the subsequent indictment, trial, and entire judicial proceeding is absolutely independent of it, and proceeds as if the coroner's jury had never acted at all. . . .

"We cannot be too jealous of the right of trial by jury, but in all cases under existing law two juries must agree before any person can be convicted of crime, without counting the coroner's jury, viz: the grand jury which presents the indictment, and the jury in the trial of the accused after indictment; so that the abolition of the jury on the preliminary inquiry, and a change as to who shall make the inquest in its stead, is not in any sense true an infringement upon the right of trial by jury which in all cases would exist if the proposed change was made."

Under the coroner system, as in actual use in the various States, much time is frequently lost by reversing what seems the proper order of procedure. A jury is summoned, witnesses are heard, and at last it is determined that a post-mortem examination is necessary, and yet, it is often of the greatest importance that the autopsy be promptly made, before decomposition is pronounced.

In a subject the fundamental principles of which are of universal application, it may be well to broaden the inquiry as to the methods adopted by the great nations of Europe which cover the important duties relegated to the coroner's inquest in England and America. For an excellent resumé of the same, I take pleasure in making reference to the valuable articles of Mr. Bell from which I have just quoted.

FRANCE.

In France two distinct and separate officers

¹ The Medico-Legal Journal, September, 1890.

take charge of all medico-legal investigations. The legal officer, attorney of the republic, is an authority not unlike the district attorney of our States. He makes a record of evidence, has the power of seizing articles or papers if connected with crime, and can temporarily hold in durance suspected persons. He may employ detectives, and is held responsible for all the legal questions involved. The scientific investigation is under the charge of a competent medical expert, especially selected for the office, who has full power, and is held responsible for a careful, scientific investigation.

GERMANY.

The present law of the German Empire was adopted in 1879. The judicial officer (*staatsanwalt*) is called the district attorney. The police are his subordinates as officers of the law in the investigation of crime. They are obliged to report to this officer all cases of sudden death or death by violence, and no interment of the body is allowed until after the consent has been obtained from this officer or a competent court. Medical examinations are made by experts especially selected for this purpose, who are summoned by the above mentioned authorities, and they in all respects conduct the examination. Upon the evidence of the preliminary examination, the district attorney enters suit before a competent court.

SCOTLAND.

The law in Scotland is analogous to that of France.

GREECE.

The system in force in Greece is almost identical with that of France. A medical officer takes exclusive charge of the medical question of the examination, and detectives, or experts trained to the business, are subject to the call of the prosecuting officer.

RUSSIA.

The officer designated in charge of the medico-legal examinations is known as judge of the institute; is an officer of the Crown, appointed in and for each district by the central governor or council of the province or state. He is possessed of large powers, and may even place in close confinement an accused or suspected person. The medical side of the case is in charge of a physician who is a salaried officer under the Crown. He conducts autopsies, and carefully reduces his examination and conclusions to writing, which he furnishes to the court, and also to the central medical council, or board, held in every province at the seat of the government, who have a power of review of the same in case doubt exists.

In 1883 a new law was enacted in Connecticut, appointing a properly qualified attorney as a coroner for each county, and a medical examiner for each town. I quote briefly from a letter written

me upon the subject by Dr. M. C. White, medical examiner for New Haven: "One feature of our new law, giving all the business of the county to one lawyer, secures immediate investigation by an experienced officer who understands law and the best methods of examining witnesses. . . . He must investigate immediately all suspicious cases. He may call a jury. All this works admirably. Three-fourths of all the sudden, violent or untimely deaths are disposed of by the medical examiners, reported and recorded, but require no legal investigation, since there is no suspicion of crime. . . . After nearly five years experience under the present law, I think the defects or questionable points are so few that we may say there is very general satisfaction with the law."

Rhode Island somewhat recently passed laws similar to those of Massachusetts, and Dr. Chas. H. Fisher, secretary of the State Board of Health, writes me "that it is a great improvement upon the preceding law and methods."

I am indebted to Dr. Samuel W. Abbott, the efficient secretary of the Massachusetts Board of Health, for most valuable information upon the working of the law as enforced in this State since 1877. I take pleasure in referring to a valuable article published by Dr. Abbott in the *Forum* for 1889, entitled "The Defects of the Coroner System." Under the new régime, about 15,000 cases of death from sudden, suspicious, violent or unknown causes have been investigated in a manner much more satisfactory than was possible under the old system. "Another important feature of the new method of procedure is the decided lessening of expense. Under the coroner system, the cost of executing the law for three years (1874, 1875, 1876) was found to be \$63,712 04, and under the new law it was \$54,509.31 for the three years (1878, 1879, 1880), a decrease of \$9,202.73, or more than three thousand dollars per year, notwithstanding an increase in the population of about eight per cent. The principal reasons for this diminished expense are found in the abolition of the jury, and in the decrease in the number of inquests. The ratio of inquests to cases investigated under the old law was forty per cent, while under the present law for the period of eleven years (1877-1888) it has been but twenty per cent, or half as many."

In review of the celebrated Barron case, in Maine, which created a wide interest outside of the State, Dr. Abbott wrote a valuable criticism, from which I quote. In the trial of one Stain, as having committed the murder, the chief question of interest was the uncertainty as to the exact cause of death: "The cashier of the Dexter bank was found dead in the vault of the bank under suspicious circumstances. Marks of violence were found upon his head. Two theories were advanced, and the little community of Dex-

ter became divided as to the question of murder or suicide. What would have been the most reasonable course to pursue under such circumstances? An immediate and thorough examination of the body, especially of the brain and stomach, would undoubtedly have settled the question of murder or suicide at once.

"What was actually done? The good-natured coroner (to use the words of the account printed at the time of the affair) deferred to the wishes of the family, and *made no autopsy*. Then came the farce of a coroner's jury. Six men sat in solemn conclave and pronounced a verdict, and of what possible value was the verdict?"

From the advanced sheets of the report of the State Board of Health, Dr. Abbott furnishes me the following statistical table:

EXPENSES OF MEDICAL EXAMINATION FOR 1889.

The total expenses of the medical examinations for the year 1889, including the cost of registration, was \$19,489.69. The average cost of each of the 1,654 medical examinations was \$11.78. In Bristol, Essex, Hampden, Hampshire and Middlesex the expense was greater, and in the remaining counties it was less, than that of the previous year.

The expenses of the four years 1885-1889 were as follows:

YEAR.	Total Number of Cases Examined.	Autopsies.	Total Expenses.	Average Expense of Each Case.
1885	1,260	165	\$16,322.54	\$12.95
1886	1,378	202	18,024.22	13.08
1887	1,556	188	18,626.26	11.97
1888	1,651	219	19,611.53	11.88
1889	1,654	216	19,489.69	11.78

In the following itemized table are presented the expenses of conducting the medical examinations in each county and for the whole State, for the year 1888:

Expenses incurred in conducting the Medical Examinations required by the Medical Examiner Laws of Massachusetts.—1889.

COUNTIES.	Number of Cases.	Autopsies.	Fees of Medical Examiners.	Mileage.	Witnesses and Clerks.	Chemists and Other Experts.	Burial, Removal, Recovery and Care of Bodies.	Incidentals.	Totals.
Barnstable	13	..	\$65.00	\$27.10	\$6.00	\$9.95	\$99.05
Berkshire	51	6	405.00	42.40	15.00	12.50	565.90
Bristol	132	7	835.00	59.40	26.00	10.40	1,148.80
Dukes	4	..	20.00	3.30	29.30
Essex	203	16	1,415.00	82.70	23.50	10.00	1,737.20
Franklin	15	..	75.00	24.30	99.30
Hampden	126	14	980.00	77.60	217.00	31.50	1,875.10

Worcester	152	12	1,060.00	115.10	100.50	..	1,388.60
Totals	1,654	216	14,380.00	\$921.89	\$1,672.30	\$1,120.00	\$1,094.25	\$71.35	\$19,259.79
Registration	229.90
									\$19,489.69

In evidence of the great value of the working of the new law in Massachusetts, I quote from an exhaustive article upon the subject, "The

Abolition of the Coroner in Massachusetts," by T. H. Tyndale, Esq.: "With the abolition of the composite functionary and of the jury, a highly-trained class of 'medical examiners,' an office gladly accepted by the first physicians in the State, we open the door for special interest in, and previously unknown penetration into, fields of detailed investigation of pathology; we have laid the foundation of a valuable body of observed facts, as shown by the publication of our Medico-Legal Transactions, contributed entirely by the medical examiners; we have attained accuracy, and we have never, since the passage of the Medical Examiner Act, failed in a single prosecution, for want, or insufficient clearness of the medical testimony. The previous statistics were—some hundreds of inquests annually—some tens of convictions. Now the great majority of prosecutions begin with the skillful investigation of trained men, acting promptly and delayed by no cumbersome, meaningless machinery, and end in convictions. . . . We have attained that greatest deterrent of crime, the chief terror to criminals—swiftness in discovery and certainty in punishment.

Incidentally, a gain dear to the lover of social cleanliness and morality has been obtained. I refer to the total disappearance from the press—except as news from other States—of the nauseous and offensive details formerly furnished by the coroner's inquest, and eagerly sought after by the prurient curiosity mongers. These changes have been wrought by a simple act, abolishing the office of coroner, and appointing for Boston two, for each other county in the State some four medical examiners whose business is solely

the physical examination and subsequent giving of testimony. . . . The new system has now

been in operation about twelve years, and has proved itself capable of exact and valuable work; no instance of willful dereliction of duty under it has taken place. It has now the commendation of judges, prosecuting officers, and the general public, and may fairly be pronounced a step in the direction of purifying the public service."

The limit of time at my disposal prevents a more detailed discussion of a subject of such vast importance, and in closing I desire to commend for earnest consideration in each of the several States the following propositions:

1. To abolish the office of coroner.
2. To dispense with jury service.
3. To separate the medical from the legal duties in all cases involving the examination into the causes of death where crime is suspected.
4. To entrust the medical examination only to competent medical officers properly trained in their work.
5. To make the number of these medical officers as small as consistent with the proper discharge of their duties.
6. To consign all questions of law only to properly qualified legal magistrates.
7. To remove the appointment of these officers entirely from the question of political consideration; and to be based only upon their possession of the requisite and proper qualifications.

Upon some basis of this character should the coroner's laws be revised. Much useless expenditure of time and money will be avoided, often great sorrow and anxiety will be prevented, and that which is of vastly greater importance, the ends of justice will be far better served.

SICKNESS AND MORTALITY IN THE ARMY OF THE UNITED STATES.

Read in the Section of State Medicine, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY JOS. R. SMITH, A.M., M.D.,

COLONEL AND SURGEON, U. S. ARMY; MEDICAL DIRECTOR DEPARTMENT OF ARIZONA.

All statistics telling the amount of disease and death in any considerable portion of the community, and showing the variations in said amount from year to year, seem properly to belong to State Medicine.

As there is no Section of military medicine and surgery in the American Medical Association, I deem it proper to present to the Section on State Medicine the following paper, in which I have collated and compared figures showing the absolute and relative amount of disease, death, and non-effectiveness in the Army of the United States.

While these statistics have been collected under conditions of considerable uniformity from year to year, yet it is to be remarked, that they

have been collected by a large number of observers, all of them medical officers of education and intelligence, yet each differing from the other in powers of observation, and in mental characteristics or peculiarities.

To some, this last named fact will make the statistics more reliable and valuable, than if they had been collated and reported by a single individual; to others, less reliable and valuable.

In 1882, I presented to the American Medical Association a paper which was printed in its Transactions, and contained the health statistics of the U. S. Army for eleven years—from 1871 to 1881 inclusive.

I now present similar data from the annual reports of the Surgeon-General for a period of nine years, from 1882 to 1889 inclusive.

TABLE I.

Showing the Sickness and Mortality from Disease in the Army of the United States during the years 1882-1889, inclusive.

YEAR ENDING	Cases per M. of mean strength reported as taken on sick report for disease.			Deaths from disease per M. of mean strength.			Deaths from disease per M. of cases of disease treated.

Total for whole period of nine years	1222	1319	1231	6.33	7.20	6.42	5.18	5.47	5.21
Total in former Reports for eleven yrs.	1551	1498	1546	8.45	11.40	8.71	5.45	7.61	5.63

The number taken sick or dying from disease, and the number constantly sick at different times, are both, in their own way, measures of the health of an army; each has its own peculiar value.

The difference between the numbers admitted on sick report for disease in the two periods tabulated in 1882 and now, might be due to difference of physique of the soldiers, to differences in the nature of their service, and to differences in the sanitary care and attention bestowed upon them.

So far as can be discovered, the material in both periods was about the same; the nature of the service was unchanged. So, reasoning by exclusion, better sanitary care and attention must have been mainly or entirely operative in causing the decrease of numbers taken sick during the period 1882 to 1889 inclusive.

Differences in the ratios of those dying from disease (not injury) per 1,000 of mean strength, might be due to these above named causes, and, in addition, to a difference in the character or constitution of each individual disease, and to better therapeutics.

As before, the first two causes may be excluded. A difference in the character of the diseases has not been proved, or even asserted; rest, the improvements in sanitation and therapeutics, as the effective factors.

The difference in the ratio of those dying from disease per 1,000 of cases of disease, would seem, besides the above named causes, specially due to either a difference in the character of the disease; that is, a greater or less tendency to death, or to better treatment, these two being either combined or complementary; one more efficient as the other is less so.

The importance of the ratios of constant non-effectiveness as a measure of comparative health, was first emphasized by the Surgeon-General of the Army in his report for 1888. The writer of the pages in that report, on the health of the Army as a whole, says: "The actual impairment of force which the Army suffers on account of sickness, as well as the relative importance of the various causes of sickness, cannot be measured with any degree of accuracy by the number of admissions to sick report, but they are shown very clearly by the aggregate loss of time which these admissions individually and collectively cause, and from this aggregate the average non-effectiveness can be accurately and readily determined."

So it is desirable to consider these data, and I have accordingly constructed a new table, containing figures relating to non-effectiveness. I have also added the ratios of "deaths from all causes," the foregoing tables including only those from disease. It is apparent that the difference between the ratios of deaths from disease, and deaths from all causes, is the ratio of deaths from injury, violence, etc.

I have deemed it best also to add the figures for some years preceding 1871—and I have commenced with 1867, because during that year the Army was reduced from a war to a peace footing, and because in that year appeared first the statistics of average or mean strength (termed in the reports "average" for the years 1867, 1868, 1869, 1886, 1887, 1888 and 1889, and "average mean" for other years), the number taken on sick report for disease, the number taken on sick report for injury, the mortality, and the constant sickness rate, all for whites and blacks separately, for the fiscal year ending June 30, to which year the rest of the report refers. Similar data have appeared in each annual report since, until 1885.

In the annual report dated October 1, 1885, and subsequent annual reports of the Surgeon-General, while the rest of the report refers to the previous fiscal year, ending June 30, the health statistics relate to the calendar year next preceding.

TABLE II.

YEAR ENDING	Ratio, per M. of mean strength, admitted for disease.			Ratio of deaths from disease, per M. of mean strength.			Ratio of deaths from disease, per M. admitted for disease.			Ratio of deaths from all causes, per M. of mean strength.			Ratio of deaths from all causes, per M. of admissions for all causes.			Ratio constantly sick, per M. of mean strength.

TABLE III.

For the four years, 1867 to 1870, inclusive . . .	2420	2407	2427	21.78	57.77	26.78	8.96	24.00	10.62	25.51	63.19	29.69	9.43	24.31	11.02	57.80	50.93	57.04
For eleven years, 1871 to 1881, inclusive . . .	1551	1498	1546	8.45	11.40	8.71	5.45	7.61	5.63	14.01	17.68	14.34	7.72	10.15	7.93	45.85	45.01	45.77
For nine years, 1882 to 1889, inclusive . . .	1222	1319	1231	6.33	7.20	6.42	5.18	5.47	5.21	9.36	10.69	9.49	6.40	6.61	6.43	43.76	43.84	43.77
For whole period of twenty-four years . . .	1667	1708	1671	11.14	23.69	12.35	6.68	13.87	7.39	15.42	28.82	16.72	8.02	14.74	8.67	44.10	42.45	43.93

This and subsequent reports also fail to give the constant sickness rates for disease and injury separately. No reason was given for these changes, nor is one apparent which is entirely satisfactory.

In consequence of them, accurate, rigorous comparison is prevented between figures of preceding and subsequent reports, and the report referred to embraces statistics for six months common to it and the previous report.

Consequent on these omissions, my table does not contain the non-effective rates for disease and injury separately, but the rate for both combined.

This same report of the Surgeon-General, for the first time gives data as to the number of days' service lost in consequence of admissions to sick report.

Explanatory of some of the figures in these tables, the text of the reports of the Surgeon-General states that 1,310 deaths from cholera occurred in 1867.

That cholera and yellow fever combined caused 681 deaths in 1868, and that yellow fever to a limited extent occurred in 1869, 1874, 1875, 1876, 1877, 1878, 1883 and 1884.

The text states that for the year 1870, "the comparatively large mortality from wounds, accidents and injuries, is explained by the Indian hostilities;" and it shows the same, in 1876, to be mainly due to the Custer massacre.

For the year ending June 30, 1884, the text reads: "It is interesting to note that not only is this the lowest death rate yet reached among colored troops since their organization, but it is the first time that the rate has fallen lower than that for white troops, the usual average difference being 3.2 per thousand of mean strength in favor of the latter class."

For the year 1885, the text says: "It is a matter of congratulation that not only the admission rate for the troops, but also the death-rate, has fallen to a lower point than at any time within the history of the Medical Department."

I remark here that my tables show that, for the succeeding years 1886, 1887, 1888 and 1889, the admission rates, though not the death-rates, for all causes, were still lower.

In the report for the year ending December 31, 1884, the text of the report of the Surgeon-General mentions the "mean strength" obtained from the reports of the Adjutant General of the Army, which varies from the "mean strength" obtained from the reports of medical officers from which all preceding rates had been calculated. The text says that the death and discharge rates in these tables, so calculated, are "higher than they should be," as the figures given by medical officers do not embrace the whole strength of the Army. The subject was only considered of enough importance to be mentioned in a footnote merely, and it is so mentioned in a footnote in the report of the ensuing year.

In the report for 1886, the matter is more fully treated of, and the difference between the two "mean strengths" is fully recognized, that given by medical officers being generally the smaller.

The reason is shown why the "mean strength" reported by the Adjutant General is the proper strength from which to calculate ratios of deaths and discharges, and these ratios are, in the 1886 and subsequent reports, calculated from the figures of the Adjutant General, while rates of admission and non-effectiveness are calculated from the figures of mean strength given by medical officers—the same is the case for succeeding years.

It may here be remarked that, from many points of view, this report of 1886 shows a distinct advance beyond its predecessors.

It is manifest that for purposes of comparison within themselves, the ratios of all reports must be calculated on similar data, and those data given.

As the data given in the reports before 1886 will not enable us to calculate ratios for these years on the figures of the Adjutant General, I have used for the ratios of every year in tables II and III, the figures given by medical officers.

The exact difference between these two "mean strengths" appears below, the figures being taken from all the annual reports of the Surgeon-General which give such figures.

MEAN STRENGTH OF ARMY.

YEAR.	White.		Colored.		Total.	
	By Returns from A. G. O.	By Reports of Medical Officers.	By Returns from A. G. O.	By Reports of Medical Officers.	By Returns from A. G. O.	By Reports of Medical Officers.
1884	23,737	21,430	2,356	2,142	26,124	24,033
1885	23,937	21,601	2,428	2,240	26,543	24,132
1886	24,103	22,310	2,636	2,416	26,995	23,572
1887	24,723	22,591	2,610	2,417	26,365	23,841
1888					26,739	24,726
1889					27,333	25,008

The difference in the ratios computed from these main strengths is given below :

YEAR.	Ratio admitted for disease by figures from Returns of Medical Officers, <i>vide</i> Table 2.	Same per Returns from A. G. O.	Ratio of deaths per M. of mean strength, from Reports of Medical Officers, <i>vide</i> Table 2.	Same from Returns from A. G. O.	Ratio of deaths from all causes per M. of mean strength, calculated from Reports of Medical Officers, <i>vide</i> Table 2.	Same from Returns from A. G. O.	Constantly sick, from Reports of Medical Officers, <i>vide</i> Table 2.	Same, from returns from A. G. O.
1884	1257	1157	7.45	6.85	10.94	10.02	44.48	40.92
1885	1118	1017	4.76	4.33	7.54	6.86	41.06	37.34
1886	1036	936	6.36	5.75	9.76	8.81	39.41	35.60
1887	1002	906	6.25	5.65	9.93	8.12	42.36	38.31
1888	1028	950	6.69	6.06	8.82	8.15	41.90	38.74
1889	1066	976	4.32	3.95	6.92	6.33	44.11	40.34

Since 1883, I have given much attention to the question of the correct mean strength of the Army. For many military posts, month after month, I have compared the figures in the reports of the Adjutant General, the figures given by medical officers, and the actual numbers on which these figures are based. It would take too much space to give all the grounds for my convictions, which I therefore merely recite, as follows:

As stated in the text of the report of the Surgeon-General for 1886, the figures in the report of the Adjutant General are the proper data on which to compute ratios of deaths and discharges.

But neither the mean strength given by the Adjutant General, nor that obtained from reports of medical officers, are correct for the calculation of ratios of admission and constant sickness.

The figures of the Post-Surgeon should be the basis with certain additions which have been habitually omitted, but which may be easily ascertained and which may in future be supplied.

In consequence of using the figures given by Post-Surgeons, without the corrections above indicated, for comparison with the statistics of other armies, all the ratios in Tables 2 and 3 are too high; and the amount of correction should be probably in accordance with the figures immediately preceding, which show the differences as computed by the different mean strengths.

In the report of the Surgeon-General for the year ending June 30, 1884, the number of cases of typhoid fever is given in the different arms of the service, and among recruits and older soldiers. No attempt is made to explain the differing conditions of these different arms; and as it will hardly be supposed that typhoid fever favors a man simply because he is a cavalry or artillery man, the remarks under this head are not of very great significance.

Elsewhere remarks are made as to the greater or less prevalence of this disease at various posts, where more or less unsanitary condition is also treated of.

The next annual report, 1885, again mentions the greater prevalence of the disease among cavalry men, and gives further details about the posts where prevalent.

Data are also given as to age and length of service of those affected.

In the same report appear tables to show the influence on mortality of rank, age, arm of service, race and nationality, and season of the year; also the relation of discharges for disability to arm of service, age, and season.

Data of a similar nature, more or less complete, appear in all subsequent reports.

The text of the report for 1889 speaks of the death rate as the lowest annual death rate in the history of the Army, and makes pertinent com-

ment on the effect produced by the number of discharges for disability on certain other health statistics of the Army.

On critical examination of the figures in Tables 2 and 3, it will be evident, that taking for a measure the admission ratios on account of diseases exclusive of injury, the figures are most favorable for the black troops for the period of four years, 1868-70 inclusive, and the period of eleven years 1871-81 inclusive; but most favorable for the white troops for the period of nine years 1882-9 inclusive, and the period of the whole twenty-four years.

Taking for our measure the mortality ratios the figures are most favorable for the white troops for each and every period given separately in Table 3.

Taking for our measure the non-effective rate the figures are slightly in favor of the whites for nine years, 1882-9 inclusive, and much more in favor of the blacks for all the other periods.

It farther appears that the death rates are more nearly equal for whites and blacks in the latter period of 9 years, 1882-9 inclusive, than in the preceding two periods. That is to say, the blacks are overtaking the whites in the race of which longevity is the goal.

As regards the admission ratios for disease and the ratios for non effectiveness, the white troops in the last period of nine years have overtaken and a little passed the blacks.

For obvious reasons, the general deductions from the figures relating to longer periods of service are more valuable than those from the figures relating to individual years; yet attention may be called to the fact that for the last year, 1889, the admission rate for disease and that for constant sickness are in favor of the black troops; while the mortality rates are considerably in favor of the white troops, while in general, the year, as regards vital statistics, was one of the best in the Army's history.

It will be further noticed that the indications from admission rate for disease, mortality rate, and constant sickness rate, are unanimously in favor of any one color but for seven years of the 24, viz: in 1874, 1878, 1881, 1885, 1887, and 1888, in favor of the white; in 1884 in favor of the black troops.

For about three-quarters of the years given, the health of the white troops has been the best, as measured by rate of admission for disease and death rate.

Measured by rate of non-effectiveness, the white troops have been less affected by disease than the blacks for twelve years, and the blacks less than the whites for twelve years.

The maximum admission rate for disease among the whites, viz.: 27.17 per thousand of mean strength, occurred in 1867; the minimum, 992, in 1887.

The maximum of the same rate among the colored troops, 28.65 per thousand, occurred in 1868; the minimum, 997, in 1889.

The maximum death rate per thousand of mean strength among the white troops, viz.: 37.15 occurred in 1867; the minimum 3.98, in 1887.

The maximum for the same rate among the colored troops, viz.: 114.46 per thousand, occurred in 1867; the minimum, 3.19, in 1885.

The maximum of non-effectiveness among the white troops, viz.: 63.02 per thousand, occurred in 1868; the minimum, 39.01 per thousand, in 1886.

The maximum of the same among colored troops, 59.28 per thousand, occurred in 1868; the minimum, 37.58, in 1880.

The maximum death rate for disease per thousand of cases of disease treated among the whites, viz.: 13.68 per thousand occurred in 1867; the minimum, 3.71, in 1889.

The maximum of same ratio among colored troops, viz.: 39.95 per thousand occurred in 1867; the minimum 2.65, in 1885.

I am unable in the reports of the Surgeon-General or elsewhere to find facts reported which adequately explain all the fluctuations in the figures of Tables 2 and 3, and without further remark I offer the foregoing figures and comments to the students of Army and other vital statistics, only adding that the figures given point unmistakably to the conclusion, that in the latter series of years tabulated, the amount of sickness and mortality was less than in the former series.

THE DUTY OF THE GOVERNMENT IN THE PREVENTION OF TUBERCU- LOSIS.

Read in the Section of State Medicine, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 5, 1891.

BY LAWRENCE F. FLICK, M.D.,
OF PHILADELPHIA, PA.

We read in the Declaration of Independence of the United States, "We hold these truths to be self-evident, that all men are created equal; that they are endowed by their Creator with certain unalienable rights; that among these are life, liberty, and the pursuit of happiness. That, to secure these rights, governments are instituted among men" All governments, indeed, which have been constituted upon the principles laid down in the great Magna Charta, have, as one of their foremost duties, the preservation of the lives and health of the people. The Common Law of England sums up the rights of individuals under three principal articles; namely: "the right of personal security, the right of personal liberty, and the right of private property;" and defines the right of per-

sonal security to consist, "in a person's legal right and uninterrupted enjoyment of his life, his limbs, his health, and his reputation."

In the earlier days of civilization many diseases were looked upon as providential visitations, and therefore non-preventable. In the Common Law of England, however, the principle that the government is bound to take every possible precaution against the spread of disease is well defined, not only indirectly by declaring for the preservation of life and health, but directly by providing penalties for persons offending against public health, or spreading such diseases as were then looked upon as contagious. The Common Law of England is operative in principle in most of the States of our Union; and its provision for life and health are affirmed in the Constitution of probably most of the States. Section 1 of the Constitution of Pennsylvania reads: "All men are born equally free and independent, and have certain inherent and inalienable rights, among which are those of enjoying and defending life and liberty, etc." The words defending life must be given a broader interpretation than mere defense against the anger of a fellow man. A reasonable interpretation makes it a defense against every danger to life for which the ingenuity of man has constructed a defense.

Modern science teaches us that many of the diseases, which were formerly looked upon as divine visitations, are but ordinary warfares between various forms of organic life for self-existence; and that when death ensues it is the going under of the weakest and the survival of the fittest. Man, the most perfect and the most intelligent of all of God's creatures, falls a victim to the onslaughts of organisms so minute that they can only be seen by the aid of most powerful lenses. What these little warriors lack in size they make up in number, and in their great power of reproduction and multiplication. The organism of man, so perfect in its construction, so complex in its machinery, and so complete in its equipment for defensive warfare against parasitic vegetation, ought never to prove the weakest in a contest with organisms so primitive in construction as are disease germs. But the tiniest and the simplest organism becomes a power when acting in concert with a large enough number of organisms of its own kind. There is a law in Nature that the smaller and more primitive an organism, the more rapid its reproduction, and in pursuance of this law, disease germs, when they once gain entrance into proper soil, multiply so rapidly that the mechanical obstruction of their presence in itself becomes a menace. It is in this their great numbers that they become great and prove themselves the victors in the contest for survival.

Ever since man has inhabited the earth he has

bethought himself of ways and means to escape and overcome disease. The accumulated thought and ingenuity of centuries has at last demonstrated to us how some diseases can at least be avoided. We now not only know that disease is mostly due to a living organism, but of some diseases we have learned enough about the organism that we can lay down pretty definite rules as to how to circumvent its development. We know what kind of soil it needs, how it is transplanted from person to person, or from persons to animals, and from animals to persons, what will readily destroy it outside of its host, how it is influenced by temperature and moisture, etc. We know, in fact, how we can prevent it from propagating any longer among us, and thus drive it entirely from our midst.

Of all diseases, the one concerning which we have this knowledge with the greatest accuracy, is tuberculosis. So dreadful has been the onslaught of this disease upon the human family that in all ages, from the days of Hippocrates down to the present, some of the brightest minds the world has produced have devoted themselves to the study of its cure and prevention. The question of its cure has not yet been satisfactorily solved, but that of its prevention has been made as clear as any problem in mathematics. We know positively that the propagation of the disease germ depends upon the contamination of the well by the sick. We know also that this contamination can only take place in a certain way, namely through the medium of broken-down tubercular tissue. We know further, that the disease germ can very readily be destroyed in this broken-down tissue before it is able to reach a new host, and that if this is done the propagation of the disease will be stopped. The question of the prevention of tuberculosis, therefore, resolves itself into a question of how the broken-down tubercular tissue given off by hundreds of thousands of persons and animals, laboring under the disease, can be destroyed before it has an opportunity of reaching and infecting others. The practical solution of this question can only be accomplished by the government.

In most of the European governments, in harmony with their political institutions, there are National Boards of Health with many dependent subordinate boards, to which is entrusted the care for the health of the people. Under our American form of government this system is not practicable, but we could have United States and State Boards of Health, which would act in harmony, and to each of which certain duties would naturally fall. There is no more reason why we should not have such Boards of Health, than there is, why we should not have United States and State Courts. We have State Boards of Health in most of the States, but we

have none in the United States. Not only should we have a Department of Health in the United States, but it should be made compulsory on every State to have such a department. The contract between the people and the government cannot and will not be carried out until the machinery for such departments has been constructed and put into operation.

The duties which would fall to a United States Department of Health in the prevention of tuberculosis, and which cannot be performed by a State Department, are the prevention of the importation of the disease from foreign countries and the carrying of it from State to State by commerce and travel. No immigrants should be allowed to enter our parts who are suffering from tuberculosis. Where such have been carried it should be seen that the ship which has carried them is properly disinfected, or at least that our own people be warned against travelling in that ship unless it is so disinfected. A thorough system of disinfection should be practiced under the supervision of the United States, on the coast vessels playing between north and south, all of which carry a large number of consumptives. All interstate railway travel should be kept under surveillance by the United States' Government, and railway companies should be compelled to provide a complete system of disinfection of all apartments occupied by persons suffering from tuberculosis. The transportation of tuberculous animals or tuberculous meat should be entirely prohibited.

In addition to these duties for the prevention of tuberculosis, which are incumbent upon the United States, because they cannot be performed by the States, there are others in which the Federal Government is co-sharer with the State Government. The Constitution of the United States gives Congress power to "lay and collect taxes, duties, impost, and excises, to pay debts and provide for the common defense, and general welfare of the United States;" . . . Under the power thus given the United States maintains an army and navy, and marine hospital service, army and navy hospitals, and educational institutions for the training of soldiers and sailors. Under the same power it could and ought to maintain a department of health, hospitals for the isolation and treatment of tuberculosis, and scientific institutions in which the disease could be studied and men given a practical training in methods of prevention. Our people have as much right to be protected against a disease which is known to be preventable as against a foreign foe.

To the State falls the lion's share of the duty in the prevention of tuberculosis. Every State in the Union should have a Department of Health, with subordinate Departments in every county of

the State. It ought to be the duty of this body to keep a record of every case of tuberculosis in the State, and of every movement of such case. Physicians ought, therefore, to be required to report every case of tuberculosis immediately upon discovery. When a case has been reported a competent officer of the State should at once be sent to the family to instruct them how to protect themselves against the disease. If they are too poor to supply themselves with the necessary means of self-protection, such means should be supplied to them, or they should be induced to remove the sick member to a special hospital for treatment. In order that sufficient opportunity be given for the tuberculous poor to be properly treated for the disease, the State ought to maintain well equipped special hospitals in various parts of the State of convenient access. Whenever a case of tuberculosis removes from a house, or dies, the State should at once, before the house can be occupied by another, thoroughly disinfect every part of it, scrape and replaster the room which was occupied by the patient, and take precautions that none of the clothing or furniture which had been used by the patient be given away or left for the use of others without first having been thoroughly disinfected. A house thus cleansed should be so recorded in the office of the department, so that any one wishing to move into it may be able to first assure himself that he runs no risk.¹ The State should also forbid and restrain the sale of food contaminated with the disease germ of tuberculosis. All slaughter houses and dairies should be inspected by competent men, and all tuberculous meat, and tuberculous milk-cows be condemned and redeemed by the State. No persons suffering from tuberculosis should be allowed to follow any avocation, in which he can contaminate the food, the implements or the wearing apparel of another. To obviate any hardships, every person suffering from tuberculosis, who is compelled to support a family, or who has anyone depending upon him, should for the time being become a pensioner of the State to the amount of his wages. Inasmuch as he gives up his earnings for the good of the public, it is but just and proper that he be supported as well as those depending upon him, at the expense of the public. I know that this will be cried down as expensive, and by some even as useless. That it would be expensive I admit; but I cannot help but feel that our present knowledge of tuberculosis will satisfy every one who will take the trouble to study the question, and whose mind is not preoccupied by a pet theory of his own, that such preventative measures would wipe out the disease.

As regards the expense, the Government, both Federal and State, is not only justified, but is

bound, by the very contract upon which it is based, to protect the people against preventable disease. All the purposes for which government is constituted may be briefly summed up under *life and its continuation for the allotted length of time without endangerment by violence or disease*. Every act of rational man is unconsciously tinted by a motive for unmolested existence. Our very physical construction is framed with this in view. Nature lets us suffer pain to indicate to us that life or limb is in danger. We have feelings of well being to show that all is right. All happiness, indeed, is dependent upon a feeling of security against danger to life for its existence. We seek to be at liberty, because we fear that restraint may prejudice our existence or that of those who are dear to us, or may place us in a position where at some time or at another we might not be able to protect ourselves or them. We seek to possess property in order that we can always supply the wants of Nature to ourselves and those dependent upon us, and that we and they can refrain from exertions when our bodies need rest. In short the pursuit of happiness may be tersely defined as the chase of the foes of life. The question of expense can, therefore, hardly be allowed to be brought forward as an argument against any preventive measures against tuberculosis. Whatever the expense might be, however, it would certainly be very small as compared to what would be saved to the people by an avoidance of the disease, even though the question of the preservation of life were left out. The return for the expenditure in the way of individual and public prosperity would amply compensate for the outlay.

It is estimated that one hundred thousand people die annually from tuberculosis in the United States.² It is well known that the largest number of victims are taken during the first half of ordinary life. Making a due allowance for the number who, being saved from tuberculosis, might fall a victim to accident or some non-preventable disease, it would, I think, be a fair estimate to assume that the average number of years of usefulness lost by each of these one hundred thousand people is ten years. We then lose every year by tuberculosis the earning capacity of one million people for one year, which, put down in dollars and cents, at the low estimate of an average earning capacity for each individual of three hundred dollars a year, would amount to three hundred million dollars. Tuberculosis is, moreover, usually a chronic disease, and of long duration. At a very low estimate, the average length of time for which a tuberculous patient is incapacitated for work before death, may be placed at six months, during which time the earning capacity of one other member of the

¹ For this thought I am indebted to my friend, J. V. P. Turner, Registrar of the Philadelphia Board of Health.

² Address on Phthisis Pulmonalis by Wm. M. Collum, M.D., Journal American Medical Association, vol. xvi, page 361.

family is at least crippled because of nursing and care required by the sick one. In this way the earning capacity of from fifty to a hundred thousand people more, for one year, is sacrificed and lost to public wealth. To the loss of time must be added the expenses incidental to sickness, which, if they averaged but fifty dollars for each sick person, would amount to five million dollars a year. It will be very apparent to every one that I have placed all my estimates too low; but even with these low estimates, the annual loss to the public wealth of the United States because of the existence of tuberculosis will reach close on to five hundred million dollars. The expenditure of one-fifth of that amount by the federal and State governments for the extermination of the disease, would completely wipe out the disease in a single generation.

I am fully aware that there are men in the medical profession, and prominent men, too, who still hold that tuberculosis is not a preventable disease, and who cry down any preventative measures on the part of the government as a useless waste of public money. If there is any doubt on the part of the government on this question, it is certainly its duty to appoint a commission to carefully examine into the question and clear up the doubt one way or another. Either tuberculosis is a preventable disease or it is not. If it is a preventable disease, the government is in duty bound to prevent it, just as much as it is bound to protect its citizens against war. The finger of science points to the fact that tuberculosis is a preventable disease. Can our government afford to wait until every skeptic in the land has been convinced that it is preventable? No; its duty begins in the very beginning, with the scientific research into the preventability of the disease, and does not end until its citizens can walk this noble land for three score and ten years, unmolested in health, life and limb by aught that can be brought under the domain and control of man.

736 Pine Street, Philadelphia.

THE DISINFECTION OF EXCRETA.

Read in the Section on State Medicine at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY GEO. M. STERNBERG, M.D.,
LIEUTENANT-COLONEL AND SURGEON U. S. A.

The Committee on Disinfectants appointed by the American Public Health Association in 1884, in its final report submitted in 1887, gives the following *general directions*:

Disinfection of Excreta, etc. The infectious character of the dejections of patients suffering from cholera and from typhoid fever is well established, and this is true of mild cases and of the earliest stages of these diseases as well as of

severe and fatal cases. It is probable that epidemic dysentery, tuberculosis, and perhaps diphtheria, yellow fever, scarlet fever, and typhus fever, may also be transmitted by means of the alvine discharges of the sick. It is, therefore, of the first importance that these should be disinfected. In cholera, diphtheria, yellow fever, and scarlet fever, all vomited material should also be looked upon as infectious. And in tuberculosis, diphtheria, scarlet fever, and infectious pneumonia, the sputa of the sick should be disinfected or destroyed by fire. It seems advisable also to treat the urine of patients sick with an infectious disease with one of the disinfecting solutions below recommended.

Chloride of lime, or bleaching powder, is perhaps entitled to the first place for disinfecting excreta, on account of the rapidity of its action.

The following standard solution is recommended:

Dissolve chloride of lime of the best quality,¹ in pure water, in the proportion of six ounces to the gallon. Use one quart of this solution for the disinfection of each discharge in cholera, typhoid fever, etc.² Mix well and leave in the vessel for at least one hour before throwing into privy vault or water closet.

The same directions apply to the disinfection of vomited matters. Infected sputum should be discharged directly into a cup half full of the solution. A five per cent. solution of carbolic acid may be used instead of the chloride of lime solution, the time of exposure to the action of the disinfectant being four hours." (Op. cit., pp. 237, 238).

The object of this paper is to inquire whether these recommendations, which were based upon the experimental data available at the time they were made, are sustained by subsequent investigations; and whether any other agents have been shown to possess superior advantages for the purpose in view.

But first we desire to call attention to another portion of the report of the Committee on Disinfectants. On page 236 the following definition of disinfection and disinfectants is given:

"The object of disinfection is to prevent the extension of infectious diseases by destroying the specific infectious material which gives rise to them. This is accomplished by the use of disinfectants. There can be no partial disinfection of such material; either its infecting power is destroyed or it is not. In the latter case there is a failure to disinfect. *Nor can there be any disinfection in the absence of infectious material.*"

¹ Good chloride of lime should contain at least 25 per cent. of available chlorine (page 92). It may be purchased by the quantity at 3½ cents per pound. The cost of the standard solution recommended is therefore but little more than a cent a gallon. A clear solution may be obtained by filtration or by decantation, but the insoluble sediment does no harm and this is an unnecessary refinement.

² For a very copious discharge use a larger quantity.

I have italicised the last sentence because I wish to call especial attention to it. I am frequently asked "what is the best disinfectant to put into a water closet." Now if a closet or privy vault is resorted to only by healthy persons and no infectious material has been thrown into it there is nothing in it to disinfect, and the recommendation of the Committee on Disinfectants does not apply to it at all. It may smell badly, and in this case the bad odor may be neutralized by the use of deodorants; or we may prevent the putrefactive decomposition of its contents and thus prevent the formation of the offensive gases given off as a result of such decomposition, by the use of antiseptics. But to accomplish this it is not necessary to sterilize the entire contents by the use of active germicide agents.

A solution of sulphate of iron or of chloride of zinc is an useful antiseptic and deodorizing agent, and the Committee on Disinfectants in making its recommendations did not intend to discourage the use of such agents. But exact experimental data showed that these agents could not be depended upon for the destruction of infectious disease germs, and the recommendations made related to disinfection in the strict and proper use of the term as above defined. This definition is now accepted by sanitarians in all parts of the world, but many practicing physicians still use the term disinfectant as synonymous with deodorant. For example, I find in a recent sanitary periodical under the heading "Medical Excerpt," an item copied from the *American Journal of Obstetrics*, to which the name of a distinguished gynecologist is attached, in which the following statement is made with reference to a much-advertised so-called "disinfectant." "As a disinfectant I have used it in my house for over a year with great satisfaction." Now the agent referred to has been proved by exact experiments to have comparatively little disinfecting power, although it is a very good deodorant. According to our definition "the object of disinfection is to prevent the extension of infectious diseases by destroying the specific infectious material which gives rise to them." Are we to suppose that the distinguished gynecologist above quoted had such infectious material in his house "for over a year" at the time he was employing "with great satisfaction" the agent he recommends? If not, the term was improperly employed for "there can be no disinfection in the absence of infectious material." I wish to emphasize this point because I have reason to believe that, in the army at least, the recommendation of the Committee on Disinfectants has led to the substitution of chloride of lime for cheaper deodorants and antiseptic agents—and especially for sulphate of iron—in latrines which are frequented only by healthy persons and consequently need no disinfection. The amount of chloride of lime issued from the Medi-

cal Purveying Depot at San Francisco during the past six months for use at military posts on the Pacific Coast, is more than double the amount of sulphate of iron; but there has been no epidemic of an infectious disease, and probably comparatively little call for the use of a disinfecting agent in the sick room. We quote again from the report of the Committee on Disinfectants:

"In the sick-room we have disease germs at an advantage, for we know where to find them as well as how to kill them. Having this knowledge, not to apply it would be criminal negligence, for our efforts to restrict the extension of infectious diseases must depend largely upon the proper use of disinfectants in the sick-room." (Op. cit., p. 237).

"The injurious consequences which are likely to result from such misapprehension and misuse of the word disinfectant will be appreciated when it is known that recent researches have demonstrated that many of the agents which have been found useful as deodorizers or as antiseptics, are entirely without value for the destruction of disease germs.

"This is true, for example, as regards the sulphate of iron or copperas, a salt which has been extensively used with the idea that it is a valuable disinfectant. As a matter of fact, sulphate of iron in saturated solution does not destroy the vitality of disease germs, or the infecting power of material containing them. This salt is, nevertheless, a very valuable antiseptic, and its low price makes it one of the most available agents for the arrest of putrefactive decomposition." (Op. cit., p. 237).

Chloride of lime is also a valuable antiseptic and deodorant, and I know of no objection to substituting it for sulphate of iron other than the question of cost. The first cost of chloride of lime, by the quantity, is about double that of sulphate of iron, but practically the difference is much greater because it is necessary to preserve the chloride of lime in air-tight packages. When exposed to the air it deteriorates in value very rapidly. It is therefore necessary to pack it in air-tight receptacles, which will not be injured by the corrosive action of free chlorine, and in comparatively small quantities, so that the contents of a package may be used soon after it is opened.

We now proceed to consider the experimental data relating to the germicide value of *chloride of lime*.

The Committee on Disinfectants gave it "the first place for disinfecting excreta on account of the rapidity of its action." This recommendation was upon experimental data obtained in the pathological laboratory of the Johns Hopkins University, under the writer's direction, and is sustained by more recent experiments made in Germany.

The experiments of Bolton, made for the Com-

mittee on Disinfectants in 1886, gave the following results: The time of exposure being two hours the typhoid bacillus and cholera spirillum in bouillon cultures were killed by a solution containing one part to 1000 parts of water (containing 0.03 per cent. of available chlorine). Anthrax spores were killed in the same time by a solution, containing 0.3 per cent. of available chlorine. Typhoid fæces were sterilized by a two per cent. solution, and in several instances by a one-half per cent. solution, but some resistant spores of non-pathogenic bacilli survived in two experiments in which a solution of 1:100 was used. In bouillon cultures to which 10 per cent. of dried egg albumen had been added, the typhoid bacillus was destroyed one-half per cent. (1:200).

Nissen, whose experiments were made in Koch's laboratory in 1890, found that anthrax spores were destroyed in thirty minutes by a 5 per cent. solution, and in 70 minutes by a 1 per cent. solution. In his experiments the typhoid bacillus and the cholera spirillum were destroyed with certainty in five minutes by a solution containing 0.12 per cent. (1:833); the anthrax bacillus in one minute by 1:1000; staphylococcus pyogenes aureus in one minute by 1:500. Experiments made by the same author on the sterilization of fæces showed that 1 per cent. could be relied upon to destroy the bacillus of typhoid fever and the spirillum of cholera in fæces in ten minutes.

Carbolic Acid.—The Committee on Disinfectants says: "A five per cent. solution of carbolic acid may be used instead of the chloride of lime solution, the time of exposure to the action of the disinfectant being four hours." This recommendation is made in view of the fact that in those diseases in which it is most important to disinfect the excreta, the specific germ does not form spores. This is now believed to be true of the typhoid bacillus, the spirillum of cholera, the bacillus of diphtheria, the bacillus of glanders, and the streptococcus of erysipelas; and it has been shown by exact experiments that all of these pathogenic bacteria are destroyed in two hours by a one per cent. solution, or less, of this agent.

Spores require for their destruction a stronger solution and a longer time. Koch found a one per cent. solution to be without effect on anthrax spores after fifteen days exposure; a two per cent. solution retarded their development, but did not destroy their vitality in seven days; a three per cent. solution was effective in two days. According to Nocht, at a temperature of 37.50 C., anthrax spores are killed by a five per cent solution in three hours.

Carbolic acid possesses the advantage of not being neutralized by the substances found in excreta, or by the presence of albumen. Thus Bolton found that the addition of 10 per cent. of dried albumen to a bouillon culture of the typhoid bacillus did not materially influence the result, the

bacillus being destroyed in two hours by a one per cent. solution.

This agent, then, is firmly established as a valuable disinfectant for excreta, but we still give the preference to the standard solution of chloride of lime of the Committee on Disinfectants for use in the sick room, "on account of the rapidity of its action," and also on account of its comparative cheapness.

At the International Sanitary Conference of Rome (1885) the writer, who was associated with Dr. Koch on the Committee on Disinfectants, presented the claims of chloride of lime, and in the recommendations of the committee it was placed beside carbolic acid with the following direction:

"Carbolic acid and chloride of lime are to be used in aqueous solution.

"Weak solutions, carbolic acid 2 per cent.; chloride of lime 1 per cent.

"Strong solutions, carbolic acid, 5 per cent.; chloride of lime, 4 per cent."

The strong solutions were to be used for the disinfection of excreta.

Creolin, a coal tar product, which is a syrupy dark brown fluid with the odor of tar, has during the past three years received much attention from the German bacteriologists. It is probably the same product which was tested under the writer's direction for the Committee on Disinfectants, in 1885, under the name of "Little's soluble phenyle." It stood at the head of the "Commercial Disinfectants" tested. The experiments made in Germany show that it is not so active for spores as carbolic acid, but that it very promptly kills known pathogenic bacteria, in the absence of spores, in solutions of 2 per cent. or less. Eismann found that a solution of two per cent. killed all test organisms within 15 minutes. Es-mann found it especially fatal to the cholera spirillum, which was killed by solutions of 1:1000 in ten minutes. The typhoid bacillus showed much greater resisting power—a one-half per cent. solution failed after ten minutes exposure. The pus cocci were still more resistant. Behring has shown that the presence of albumen greatly diminishes its germicide power. As a deodorant it is superior to carbolic acid, and on this account is to be preferred in the sick room. A recently prepared emulsion may be used to disinfect the liquid excreta of cholera or typhoid patients, in the proportion of four per cent., two hours time being allowed for the action of the disinfectant. The experiments of Jaeger upon pure cultures of the tubercle bacillus attached to silk threads were successful in destroying the infecting power of these cultures, as tested by inoculation into the anterior chamber of the eye of a rabbit, when solutions of 2 per cent. were used.

The value of this agent as a disinfectant is then fully established; as to its cost in compar-

ison with the agents heretofore mentioned I am not informed.

Quick Lime.—Experiments made in Koch's laboratory in 1887 by Liboriws led him to place a high value upon recently burned quick lime as a disinfectant. More recent experiments by Jaeger, Kitisato, Pfuhl, and others have shown that this agent has considerable germicide power, in the absence of spores, and that the value which has long been placed upon it for the treatment of excrementitious material in latrines, etc., and as a wash for exposed surfaces, is justified by the results of exact experiments made upon known pathogenic bacteria. The germicide power of lime is not interfered with by the presence of albuminous material, but is neutralized by phosphates, carbonates and other bases, and by carbonic acid.

In the writer's experiments a saturated aqueous solution of calcium oxide failed to kill typhoid bacilli; but when suspended in water in the proportion of 1:40 by weight this bacillus was killed at the end of two hours. Anthrax spores were not killed in the same time by a lime wash containing 20 per cent. by weight of pure calcium oxide. According to Kitisato the typhoid bacillus and the cholera spirillum in bouillon cultures are destroyed by the addition of 0.1 per cent. of calcium oxide. Pfuhl experimented upon sterilized fæces to which pure cultures of the typhoid bacillus, or cholera spirillum were added. The liquid discharges of patients with typhoid fever or diarrhœa were used for the purpose. He found that sterilization was effected at the end of two hours by adding fragments of calcium hydrate in the proportion of 6 per cent., and that 3 per cent. was effective in six hours. When a milk of lime was used which could be thoroughly mixed with the dejecta the result was still more favorable. A standard preparation of milk of lime containing 20 per cent. of calcium hydrate killed the typhoid bacillus and the cholera spirillum in one hour when added to liquid fæces in the proportion of 2 per cent.

The experiments with this agent show that time is an important factor and that much longer exposures, as well as stronger solutions, are required to destroy pathogenic bacteria, than is the case with chloride of lime. For this reason we still give the last named agent the preference for the disinfection of excreta in the sick room. But in latrines the time required to accomplish disinfection is of less importance, and *we are disposed to give recently burned quick lime the first place for the disinfection of excreta in privy vaults, or on the surface of the ground.* It may be applied in the form of milk of lime, prepared by adding gradually eight parts, by weight, of water to one part of calcium hydrate. This must be freshly prepared, or protected from the air to prevent the formation of the inactive carbonate of lime.

According to Behring lime has about the same germicide value as the other caustic alkalies, and destroys the cholera spirillum and the bacillus of typhoid fever, of diphtheria, and of glanders, after several hours exposure, in the proportion of 50 cc. *normal bauge* per litre. Wood ashes of lye of the same alkaline strength may therefore be substituted for quick lime.

Finally, it must not be forgotten that we have a ready means of disinfecting excreta in the sick-room, or its vicinity, by the application of heat. Exact experiments made by the writer and others show that the thermal death-point of the following pathogenic bacteria, and of the kinds of virus mentioned is below 60° C. (140° F.): Spirillum of cholera, bacillus of anthrax, bacillus of typhoid fever, bacillus of diphtheria, bacillus of glanders, diplococcus of pneumonia (M. Pasteur), streptococcus of erysipelas, staphylococci of pus, micrococcus of gonorrhœa, vaccine virus, sheep pox virus, hydrophobia virus. Ten minutes exposure to the temperature mentioned may be relied upon for the disinfection of material containing any of these pathogenic organisms—except the anthrax bacillus when in the stage of spore formation. The use, therefore, of *boiling water in the proportion of three or four parts to one part of the material to be disinfected* may be safely recommended for such material. Or better still, a 10 per cent. solution of sulphate of iron or of chloride of zinc, at the boiling point, may be used in the same way (three parts to one). This will have a higher boiling point than water, and will serve at the same time as a deodorant. During an epidemic of cholera or typhoid fever such a solution might be kept boiling in a proper receptacle in the vicinity of the hospital wards containing patients, and would serve to conveniently, promptly, and cheaply disinfect all excreta.

THE SANITARY AND UNSANITARY RELATIONS OF UNDERGROUND WATERS.

Read in the Section of State Medicine, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY S. H. BRYCE, M.D.,
OF TORONTO.

Gentlemen:—It is not my intention to deal at any length with this subject, but rather to present some of the principles to be observed in the selection of drinking-waters.

Much has been said with regard to the dangers of drinking water from wells; but it has not been until recently that the differentiation has been made as regards wells that are dangerous and those that are healthy.

As a general principle, it may be said that practically all *really* underground waters are sanitarily good; but it must be clearly understood what is meant by an underground water. For instance:

1. A water lying in a shallow dug out in prairie or bog land, down only to the impervious clay or rock below, cannot fairly be called underground water.

2. Neither can a well down even into a true water-bearing stratum of sand or gravel, be called an underground water, if the water of the upper organic soil layer is allowed to percolate toward the well laterally, without really moving downward through the underlying beds of clay loam, sand or gravel, which serve to sterilize the waters in their passage downward.

3. Neither can a well be called underground if, as is commonly the case, the well is covered with loose boards, or a wooden framework, thereby allowing the filth washings from the surface of the boards to be carried down through cracks into the water of the well.

Carl Fraenkel and others have carefully examined into the water of pit-wells, and such have by Pflügge been called "hygienic monsters"

Clearly, then, underground waters mean those which have primarily fallen upon the surface, have there been contaminated with soil microbes, but which have, in their passage downward, through percolation to the water-bearing zone situated on some impervious stratum, been purified by the several natural agencies which are at work.

Of these, doubtless, the one of greatest importance is the mechanical retention in the upper layers, of the grosser organic matters, for instance those of sewage on a sewage farm.

I have found that at a sewage farm, the upper circle or two of the bed of sand has retained practically all suspended organic matters, and that even soluble organic matters are gradually abstracted by capillary adhesion from waters as they pass downward.

In addition, however, to this cleansing action of capillarity, we have at work, under favoring conditions, the destructive action of bacteria. With various kinds of organic matters, putrefaction bacteria deal largely, but their work, while purifying to the soil, may result in emanations of an extremely injurious character. In order that this decomposition may go on rapidly and without pernicious results, intermittency of deposit of organic matter on the surface and the penetration of air with its oxygen into the soil is required, in order that the nitrifying germ, proper, may carry on its beneficent work.

Manifestly, therefore, we have in towns conditions where, with the permanent presence of masses of organic matter in back yards and in privies, waters may move laterally or from the surface, carrying to the largest extent their solubility admits of, organic materials to underground strata, which, appearing in wells, and there coming into contact with oxygen, supply conditions for the free multiplication of germs borne in from the surface or the air, and hence waters that have been sterile as underground streams, and loaded with soluble organic matters, become culture media for certain pathogenic bacteria in those seasons of the year when the water temperature makes their development abundant. Every one is familiar with wells dangerous only in the later summer months when deep, or from spring or early summer, when their water reaches a higher temperature.

Much interest has for many years attached to the experiments of Pettenkofer with regard to the rising and falling of underground waters, in their bearing upon the increase in the mortality from filth diseases, notably of typhoid fever. It has been assumed that he was correct in saying that after a summer lowering of the ground water, and then a rise with autumn rains, typhoid invariably increased.

Now, with regard to this, as with so many other conditions, individual local circumstances will decide whether or not he is correct. For instance, Buck and Franklin have laid special stress on *wetness of soil* in general, and the effect of highness or lowness of the *subsoil water*, as increasing *cholera infantum*. Hirsch, on the other hand, examined the relationship between the number of cases of cholera infantum and the level of the subsoil water at Berlin, from 1877 to 1882, and concluded that the height of the subsoil water in Berlin gives no measure of the rate of mortality. Now if we look closely into the facts there, his conclusions are as we would expect. The city is

largely supplied with public water from the river sources, and naturally we find that during periods of high ground water, the rivers become increased in their volume, and instead of the drinking-water being more impure at such times, it would be less so.

But the case is different where well water is used. During the periods of dry weather, as the water in the superficial soil layers has gradually passed downward, it has been followed, according to the permeability of a soil, by atmospheric air, thereby extending the line of organic decomposition downward—this, however, being limited usually by the upper 4 or 5 feet.

What then takes place when heavy rains come? The first result is that the upper permeable bed, loaded with bacteria from free decomposition of organic matters, becomes saturated with moisture, while privies also, which have during the dry weather lost most of their fluid contents by evaporation, likewise become surcharged with moisture. The water from both these supersaturated sources moves along laterally downward toward the wells, as the lowest point, and loads them with soluble organic impurities, and with putrefactive and nitrifying bacteria; in addition to suspended impurities washed in from the surface. This causes disease, beyond question; but this is not due to the rise of ground water necessarily, since, as all know, the actual rise, in other than shallow subterranean water-streams and in springs, does not take place till weeks, or even months, after the spring or autumnal heavy rainfalls.

We, therefore, can see that the conditions governing the purity of water supplies from ponded streams and small lakes, are very different from those governing well waters, as in pit-wells. When the first are most foul, the latter are often least so.

The question, then, of the use of underground waters, is of a much wider nature than that relating merely to pit-wells in town and country.

Falling upon pervious upper soil and upland and cultivated fields, the rain forms those great reservoirs upon which river and lake supplies, as also that of ordinary wells, depends. Springs on the hillside are the index of their existence, and to these streams must we look for a pure water supply, obtained under conditions widely different from those we have just referred to.

Analyze these spring waters before contaminated by surface filth, drive an iron pipe down to this water-bearing stratum, and we find a water in all cases absolutely free from bacterial life, and those conditions which make pit-wells under ordinary conditions, such dangerous sources of supply.

As the rivers, in recent years, have been falling during the long summer, through the loss of the upland forests which formerly held back the water, and whose absence likewise creates long summer droughts, relieved at most by destructive

thunder-storms, we have found ourselves depending upon ponded waters, becoming more impure by evaporation, lessening their amount, or upon rivers becoming more polluted by this lessened amount, together with increasing pollution by our growing towns. We are hence forced to turn our attention to these underground waters, sometimes, it is true, somewhat excessive in hardness, but always sterile, and supplying to artesian wells, driven wells, water-galleries of perforated pipes, and springs carefully collected and protected against surface pollution, while the utilization of such will do much to solve the questions both of water supply and sewage which, upon this rapidly populating continent, are to-day of more importance than probably all other health problems combined.

SECTION OF OPHTHALMOLOGY.

RECORD OF THE MEETINGS.

DR. LEARTUS CONNOR, Chairman.

DR. T. E. MURRELL, Secretary.

The sessions of this Section were held in the afternoon of May 5th, 6th and 7th, in the Medical Department of Georgetown University.

The chairman opened the first meeting with an address which contained very valuable suggestions in regard to promoting the interests of the Section. After the reading of this paper, upon motion, a committee of three was appointed to consider the suggestions in the Chairman's Address; the Chairman to be one of the committee.

The committee, consisting of Drs. Geo. E. Frothingham, Edward Jackson and Leartus Connor, reported on the second day as follows:

Gentlemen of the Ophthalmological Section, American Medical Association:

Your Committee, to whom was referred the Chairman's Address, begs leave to report upon his suggestions, by recommending the Section to adopt the following:

First, That the Section appoint an Executive Committee of three, whose general duties shall be to look after all matters pertaining to the development of the Section, not already in the hands of existing officers. When first appointed the members of this Committee shall serve for three, two and one years respectively, the yearly vacancy occurring thereafter shall be filled by the retiring chairman of the Section. Should other Sections appoint similar committees, it shall cooperate with them in all efforts to promote the interests of all Sections. It shall hold a yearly meeting, previous to the beginning of the sessions of the Section, at an exact date and place to be named by the Chairman of the Committee, and at such other times and places as the Committee may deem best for the promotion of the growth of the Section.

Second, That the Executive Committee be instructed to formulate and execute the plans needful for securing the re-publication from THE JOURNAL of the work of the Section, including papers with the discussions thereon, a complete list of all members of the Association who are active workers in ophthalmology, and such other facts as may be necessary for the completeness of the publica-

tion, as the names and addresses of the officers, names and addresses of the Executive Committee, a copy of this report, etc. It shall carefully edit the papers, discussions, list of members, etc., so that they may appear in correct form, when given to the public as the work of this Section. It shall finally secure such mechanical execution of the work as will render its appearance creditable to the Section.

Third, That the Executive Committee shall arrange for a Section dinner on the evening of the second day of the Annual meeting, at the usual dining hour of the place of meeting, at a price not to exceed two dollars, each member paying for his own ticket.

Fourth, It shall secure the names and addresses of all reputable ophthalmologists in North America, and use all reasonable measures to secure their coöperation in the work of the Section.

Signed, GEORGE E. FROTHINGHAM,
EDWARD JACKSON,
LEARTUS CONNER,
Committee.

On motion, this report was adopted unanimously, and the Chairman instructed to appoint the Committee. He named, in obedience to these instructions, the following as its members.

For three years, S. C. Ayres, 64 W. 7th St., Cincinnati, Ohio.

For two years, F. C. Hotz, 103 State St., Chicago, Ill.

For one year, Edward Jackson, 215 S. 17th St., Philadelphia, Pa.

S. C. Ayres being first appointed, was made Chairman of the Executive Committee.

On the afternoon of the second day, as fixed by the By-Laws, the Committee on nominations, consisting of Drs. F. C. Hotz, S. C. Ayres and J. J. Chisolm, reported the following officers for the ensuing year: Dr. J. L. Thompson of Indianapolis, Chairman; Dr. Geo. de Schweinitz of Philadelphia, Secretary.

Dr. S. C. Savage introduced the following resolution which was adopted.

Resolved, That the Section on Ophthalmology adopt the nomenclature introduced and applied to muscular insufficiencies by Dr. George T. Stevens.

Dr. Edward Jackson introduced the following resolution concerning the numbering of prisms, which was jointly agreed upon by himself, Dr. Swan M. Burnett and Dr. Alex Randall:

Resolved, That the Section on Ophthalmology of the American Medical Association, adopt and recommend as a standard or unit prism one which gives a deflection of one centimetre at the distance of one metre, and that this measurement may be taken on a plane up to No. 20. For higher numbers it is suggested that they be taken on the arc, or expressed in equivalent tangents. It also recommends to opticians and the profession for measurement the prismometer of Mr. C. F. Prentice.

The resolution was adoption by the Section.

Dr. Alex Randall exhibited the prismometer of Mr. Prentice.

Dr. S. C. Ayres exhibited a book he arranged for ophthalmologists entitled, "Oculist's Index Rerum." It is so arranged as to furnish a complete and handy index to every case in the case book according to classification. It will index

twenty thousand cases, and is so simple and clear in arrangement as to be invaluable to any one who writes for publication the interesting cases in his practice, or compiles statistics. The book is published by J. H. Chambers & Co., of St. Louis.

At the conclusion of the programme the Chairman returned thanks to the members of the Section for their courteous bearing, and in turn, upon motion of Dr. Swan M. Burnett, a vote of thanks was tendered the Chairman and Secretary.

T. E. MURRELL, Secretary.

OTHER METHODS OF PROMOTING THE DEVELOPMENT OF THE SECTIONS.

Suggestions to the Section on Ophthalmology of the American Medical Association, at its meeting in Washington, D. C., May, 1891, by the Chairman,

LEARTUS CONNOR., A.M., M.D.,
 OF DETROIT, MICH.

The future of the American Medical Association rests upon the works of its Sections. If this stands the test of criticism by intelligent medical men, then will the Association attract to its membership an increasingly large number of representative physicians from every portion of the American Continent.

The history of this Section is well known. From a membership of a dozen it has increased to over one hundred. From material insufficient for a few hours it has grown to a stage when its wealth of material taxes every energy for its profitable disposition during the longest obtainable sessions. Its career has been checkered by numerous disturbing and destructive forces, but having continued to develop in spite of these, and by their aid, it may confidently anticipate a future more useful to our science, more helpful to ourselves and more honorable to the profession. During the time allowed for remarks by your chairman, it were impossible to give an exhaustive account of the ophthalmological work accomplished during the past year. In general, we may say that no "epoch making discovery" has appeared, though every department exhibits important contributions. Some of these clear away obstructions, others add new facts, new principles and new processes. The true has been more firmly established, the doubtful rendered possible or certain, and some steps taken into the unknown.

The thirty-four papers presented at this meeting will unquestionably still further enrich our literature and render future work more satisfactory. I refrain from the discussion of any related topic in order that more time may be reserved for the reading and discussion of these papers. I am the more disposed to this course because I regard the position of chairman of this Section, as one calling for an undivided service to the interests of the entire Section. He is simply the servant of the Section. In this service I have learned numerous facts, from which I present certain suggestions:

First.—By rule of the Association, our papers and discussions are published in *THE JOURNAL*. This gives them a wide circulation among the profession and a permanent place in the volumes of *THE JOURNAL*. Some papers are reprinted at the expense of their authors and distributed among their ophthalmological friends. Thus, with a large and increasing circulation of *THE JOURNAL*, our contributions are disposed of in a profitable manner. But it has occurred to me that other useful purposes might be accomplished by an extension of their publication. To illustrate: The American Laryngological Society first publishes its papers and discussions in the *New York Medical Journal*. This being completed, they are republished in a separate form, as the transactions of this society. With these is printed a list of the members of the society, its rules and other important items of information. In like manner it is suggested that this Section arrange to have its papers and the discussions thereon, republished from *THE JOURNAL*, and with them printed an accurate list of all the members of the Association interested in

ophthalmology, and such other facts as would promote the interests of the Section. Such a republication would be a great convenience to us individually, and to all our fellow workers throughout the world. Life is short, its duties exacting and multiform, so that to be most valuable, work must be presented to busy men in a form readily accessible, else it will fail of the immediate accomplishment of its mission. The expense of this republication need not be great, and it is thought would be cheerfully met by such members as are interested in the development of the Section. The volumes also would have a limited sale that would partially meet the publication expenses. It seems clear that such an arrangement would attract other valuable workers into our ranks, and so augment the strength of the Section. In such a republication our work would stand out boldly as a unit, for the criticism of our colleagues. Individuals knowing that their papers were thus to receive added attention from experts, would be still more careful to prove their work several times ere bringing it before such a tribunal. Those having done work which they were confident would stand this added test, would gladly embrace the opportunity, and so our Section work would rise to progressively higher planes.

Were the Section to successfully inaugurate this change, others would follow, until each Section of the Association had its distinctive volume of transactions. Such a result must bring increased prosperity to both Association and Journal. The world at large estimates the Association, mainly, by what it sees of its Section work. THE JOURNAL stands or falls by the quality of the material sent it by the Sections. Hence of necessity, the backbone of both Association and Journal is constructed of the several Sections. THE JOURNAL has wonderfully aided the Sections and the proposed change must favorably increase this aid.

Second.—There should be made, subject to yearly revision, a list of all members of this Section. It should include all workers in this field who are members of the Association. Such a list would enable the members to know their fellow workers, and to exert such an influence as would secure from each his best work for this Section's meetings. Instead of being lost in a list of several thousand members, our fellows would have a distinctive individuality of their own. As already suggested, this list could be issued with the proposed volume of yearly transactions, and be compiled by the same publication committee. Such a list I have compiled, as completely as was possible, and present it to the Section for the use of the officers and the convenience of the fellows. All reputable physicians interested in ophthalmology can, by joining the American Medical Association, become members

of this Section. If only the proper measures be adopted, it is possible that most reputable ophthalmologists in the United States will find membership in this body both profitable and pleasant to them.

Third.—Granting that the value of the Association meetings depends mainly upon the work of the Sections, it follows that the time given for Section work should be fully adequate for doing it in a perfectly satisfactory manner. There may be difference of opinion on this point, but it does not seem that less than six hours daily, will meet the present needs of this Section. When it becomes known that such a space of time is devoted to the reading and discussion of ophthalmological questions, these meetings will possess greater attraction to earnest students. They will see in attendance upon them adequate compensation for the fatigue of long journeys, the loss of private business and the corresponding diminution of income, the expenditure of considerable sums of money called for by such journeys and protracted absence from home. To secure larger attendance it must be shown that these meetings are worth more than the cost of time, of labor or of discomfort. The increase of the hours devoted to actual work as suggested would, I am certain, so increase the profit of these meetings as to outweigh the necessary cost, to a far larger number than at present. I am aware that the time devoted to the Section meetings is regulated by the Association, but it is certain that the agitation of the matter by earnest members of the Sections would meet a sympathetic response, and the problem be solved to the satisfaction of all.

Many thoughtful observers unite in the conviction that all interests would be best advanced by a very considerable shortening of the general sessions of the Association. They believe that most of the business and discussions of these sessions were better done by committees, and the time thus saved be given to the Sections. With six full working hours daily, free from all disturbing influences, the Sections would quite astonish both themselves and the Association, with the results they would attain—results helpful and uplifting to all members of the Sections, to the Association as a whole, to its Journal and to the profession at large.

Fourth.—Social commingling has its proper place. Each of us has felt the enlargement due to the personal contact with a fellow worker formerly known to us only by reputation. To have grasped his hand, to have looked into his face, to have listened to his voice, and to have been infected with his enthusiasm, has lifted us above our former plane and made better men of us, by the inspiration to do better work, in the future. Especially is this true, if the circumstances are favorable for the unbending of the severer men-

tal processes, and the outward expression of the heart qualities inherent in every true man. To promote this end in an increased degree, it is suggested that this Section dine together on the evening of the first day. It were better that the hour were the usual dining hour of the place of meeting. The price of the dinner tickets should be limited to a modest sum—say two dollars each, each individual paying for his own ticket. Doubtless, if this Section found the practice pleasant and profitable, other Sections would follow, until at last the entire Association, divided by groups according to their personal tastes, would dine together. An incidental advantage of this plan is the diminution of the labor and expense attending the entertainments given the Association, by the citizens of the cities visited.

Fifth.—in many ways it would facilitate the development of this Section, to have at its disposal a complete list of all reputable physicians practicing ophthalmology in North America. This Section desires the hearty coöperation of all such, but is unable to take all the steps needful to secure it, until it has ascertained their existence and location. In this view of the situation, the preparation of such a list was commenced. It was thought that the individuals upon this should be endorsed by one or more well-known ophthalmologists, and be either a member of a State Medical Society or eligible thereto. The first step in executing the plan was to secure the aid of some ophthalmological friends in making the first list of ophthalmologists. Fortunately, I was able to secure the list prepared last year by the former President of this Section and the Secretary, Drs. Ayres and Gardiner. This included about 125 names, located in every portion of the United States. A printed copy of this was sent to each gentleman upon the list, with the request that he make such additions to it as would enable it to include every reputable physician practicing ophthalmology. On their return these names were combined, and assorted alphabetically by States. Those in each State were sent to one or more well known ophthalmologist in that State, for revision according to the plan stated. On the receipt of these revisions, a new complete list was made, and sent to such ophthalmologists as were known to be familiar with the profession of several adjacent States, for further correction. From the returns of these lists, a last one was made and sent to the Secretary of each State Medical Society, with the request that those names be erased who were not members of the State Society, and were ineligible, and that others be added, if members of the State Society or eligible thereto, and regarded as reputable ophthalmologists. The list for New York includes those recommended by both State Societies. For our purpose it was deemed best to ignore the difference between these bodies. We

simply wanted a list of all reputable ophthalmologists, selected by competent judges. Should any person desire to eliminate those belonging to the old or the new Society, he can do so by comparing this list with that of either Society. It thus appeared that the process by which this list was constructed was tedious and complicated. The names on it have been placed there by one or more ophthalmologists, and further endorsed by the Secretary of the State Society in which the individual lives. The work was only possible through the coöperation of these numerous correspondents, and to each I publicly return my hearty thanks. Because of its incompleteness and probable errors, I have refrained from scattering it among our Fellows. If this Section, by a committee, desires to further perfect it, I shall be glad to render what assistance I may. If it regards it inexpedient so to do, I shall leave a copy with the officers of the Section, for their aid in the prosecution of their work, after I have made the final correction of the proofs, by aid of the members present.

Finally, I direct attention to the fact that so gradual has been their growth, that the Association has but partially modified its organic laws in accord with the character and importance of the Sections. Old customs by their very inertia have continued to exist when new ones are called for by the change of conditions. That the Section on ophthalmology may do its part toward making the needful changes, necessary to place the Association as a whole upon a platform in full accord with the conditions existing to day, I venture to suggest: 1. The appointment by the Section of an executive committee of three, to join with a similar committee from each of the other Sections (when said sections shall have appointed such a committee) in forming a Council of the Sections. The object of this council shall be, in general, to secure united action by the Sections upon all matters relating to their common interests, especially to secure such action as will promote their normal development. Among these may be mentioned: the republication from *THE JOURNAL* of the work of each Section with a list of its members; an increase in the amount of time devoted to Section work; a diminution of the time and work of the general sessions; and a promotion of the social intercourse of the members of each Section with each other. Doubtless other and more important questions would come before this Council. The principle, however, would be unchanged, viz., the desirability of such organization of the Sections as would enable them to plan such changes in the conduct of the affairs of the Association as they may, by study and consultation, find needful to ensure their most complete development. The future of the Association rests with the Sections. Is it not time for them to realize this responsibility and

intelligently move forward to meet it, in accord with the state of the medical profession as it exists to-day?

If appointed this year, our executive committee could promote the formation of similar committees by the other sections, and so lead the way for the perfection of the Section Council. It could take the steps needed for the republication of our own transactions; it could arrange for a Section dinner; for the annual publication of a list of our own members; for an increase of time given to Section work. Other things doubtless it would find within its power by which it could advance the interests of this Section. As the most perfectly specialized department of medicine and surgery, it seems meet that it should take the first steps in the working out of a better future for not only itself but for the entire Association, including its Journal and the profession at large, a future in which the Association will attract to its membership every reputable physician practicing in North America, a future in which every department of the art and science of medicine shall be impelled forwards by the combined momentum of all to a degree hitherto unknown, a future in which our power shall be recognized in the laboratory, in the hospital, in the college, among the sick, and the unfortunate, but among the people as a whole as represented in legislative halls and by every intelligent individual throughout the land.

PHYSICAL CAUSES OF HEART DISEASE, AND TREATMENT.

Read before the Section of Internal Medicine, at the Tenth International Medical Congress, Berlin, 1890.

BY EPHRAIM CUTTER, A.M., M.D., LL.D.,
OF NEW YORK.

Corresponding Member Belgian and Italian Microscopical Societies;
Member of American Society of Microscopists; President American Branch Society of Science, Letters and Art, of London.

Things that increase the work of the heart are physical causes of its diseases, as follows:

A. Hæmic. That is from the blood and its vessels, including the heart itself. *B. Tropho-pathic*—from the food, to-wit: gases, fermentation, fatty and fibrous degeneration, catarrhs. *C. Gynecologic*—from reflex uterine irritation. *D. Motio al*—as running, lifting heavy weights and climbing ascents. *E. Emotional*—as passions. *F. Postural.* *G. Heredity.* *H. Inflammatory,* etc., to name no more.

The limits allow only a brief discussion of the causes A, B, C and F. Perhaps it is best, as D, E, G and H are well understood.

We start with the idea that in health the heart can do its great work. We emphasize great, for we think few realize its greatness. It is great because, 1, unceasing; 2, of the weight of blood carried; 3, the distance carried; and 4, the mi-

croscopic smallness of the difference between the size of the capillaries and the average red corpuscles. All are familiar with the restless labor and the immense weight of blood the heart carries, so we will speak of 3 and 4. Some years ago a dentist of Boston, Dr. G. B. Harriman, said that the arteries, veins and capillaries in man, if able to be removed and connected with each other, would reach twice round the earth—that is, 48,000 miles. This was doubted, so he and I verified his statement by immersing our nude bodies in a bath-tub filled with water, and calculated the average displacement of an adult male weighing 150 lbs. to be 4,650 cubic inches. Next we calculated there would be 3,000 capillaries laid side by side in one square inch; in a cubic inch 9,000,000 capillaries one inch long, or in round numbers, 140 miles English.

On a very moderate basis, we thought we could reckon human bodies to be one-quarter capillaries. One thousand cubic inches of capillaries would give the enormous mileage of 142,000 miles, on a modest estimate, or nearly thrice the first estimate, which is overwhelming to the human intellect. But cut these figures down by other estimates, still they will not do away with the tremendous distance that the blood has to travel to do its work, and which should be borne in mind in the clinical estimates of heart disease. Suppose we come down to 1,000 miles as the estimate. It is work to circulate fluid through a tube 1,000 miles long. In health the heart does this work, but let there be added resistance from increased viscosity, and from changes in the walls of the vessels that make them rough and narrower, then think how much harder the heart has to work. The so-called "trip-hammer" beats of the heart have been found to occur where the circulation has been blocked by emboli, and are probably simply due to the heart's own efforts to propel the circulation normally.

The Heart an Autonomy.—That is to say, the heart governs the force and frequency of its pulsation very much like the governor of the steam engine—only the heart's governor lies in the ganglionic nerves that are situated in the base of the heart. They do not celebrate like the nerve centres of the cerebrum, but they act in their way as the cerebral nerve centres act. I have had the heart beat regularly for twelve hours after entire removal from a mud turtle.

We think a careful study will sustain the autonomy of the heart as an independent nerve centre, but time forbids more explication here.

The clinical point here wished to be made, is that if the circulation is partially obstructed, whether from viscid blood or roughened vessels, the heart will have to beat harder to maintain the circulation, and thus become diseased by growing larger, as any muscle grows bigger by over-use, and if too long continued, atrophied, painful,

crampy from nervous prostration, as in writer's cramp.

The heart's work is great because there is little room for the blood corpuscles to flow through the capillaries.

What is the difference between $\frac{1}{3000}$ inch, the diameter of a capillary, and $\frac{1}{3200}$ inch, which is a little less than the average diameter of the red blood corpuscles. (It is not necessary to consider the white corpuscles, for they break up so easily into two, three, and even five segments, that they readily penetrate the capillaries.) Answer: $\frac{1}{40000}$. So that all the leeway the average red corpuscle has is less than $\frac{1}{40000}$ of an inch. A very small margin, and one liable to be used up because of its excessive microscopic minuteness. Let the blood become more viscid, or contain foreign bodies like those named, and how easy it must be to increase the work of the heart, and thus cause disease, as when the cardiac nerve centres find out there is obstruction, they use force to overcome it.

A. *Hæmic obstructions are:*

1. *In the blood.* 2. *In the blood-vessels.*

1. *In the Blood. The Morphology of the Blood in Rheumatism.*¹

Red Corpuscles: Color usually impaired, not always; coloring matter not so firmly held as in health. Are adhesive, sticky, often drawn out into elongated lozenge-shaped bodies with pointed ends, and sometimes filamentous, joining with one or more of their fellows. They clot in wirrows, ridges and huddled masses; sometimes quite formless. This is caused by the massive fibrin filaments holding them fast, as it were, in their firm meshes. The same thing is seen in consumptive blood, but to a less degree.

White Corpuscles: Usually enlarged, adhesive, sticking to each other and to the red corpuscles, and matters found in the serum. Indeed, it seems to be the office of the white corpuscles, so far as possible, to swallow and envelop any foreign substance that may find its way into the blood. Thus we find crystalline matters in the white blood corpuscles in rheumatism, though not always. They undergo amoeboid movements as in healthy blood, they have independent locomotion. Disease does not seem to impair their automatic movements. Often they are increased in number. If there is fatty degeneration going on, they will be found to contain fat in globules.

The Serum. Fibrin Filaments.—In massive, strong and sticky threads, in abundance—in meshes, which are finer than in health, visible plainly, strong, and hold the red corpuscles like prisoners—in skeins, like tangled skeins of silk—in masses forming thrombi which, when fastened, form emboli. These thrombi are apt to involve and embrace white and red corpuscles and crystalline bodies to be named below. Sometimes the fibrin filaments are found in large round strings, curled fancifully by the motion of the blood stream, and looking like the mycelial filaments of vegetations, from which they can be distinguished by an absence of entire cylindrical outline—ragged, broken edges here and there, and dichotomous and polychotomous divisions of the trunk, different from vegetations of syphilis, for example. It is the presence of these fibrin filaments that makes the blood ropy, adhesive and sticky. They have the tendency to block up the blood stream, and besides to be locally deposited in the tissues, specially when the circulation is sluggish, as near the extremities and the joints."

Crystalline Bodies, or Gravel of the Blood.—"These are numerous and readily recognized; some of them are as follows: 1. Uric acid and urates of soda. 2. Phosphates—specially the triple phosphates of lime and soda. 3. Oxalate of lime. 4. Cystine. This is quite common and easily detected. 5. Carbonate of lime, rare. 6. Stelline and stellurine. These occur mostly in granular form in the serum, but in old cases, where the system is saturated, they are crystalline. 7. Black, brown, aniline blue, bronze, orange, red and yellow pigments in the form of flakes or small masses are common in rheumatic blood, and may be termed gravelly matters that should have been eliminated by the kidneys or bowels, or skin.

"Latent Condition of the Characteristics of Rheumatic Blood.—The morphology of rheumatic blood exists in a latent condition in persons apparently well; but when they are exposed to cold, the blood-vessels contract, catch and detain these abnormal elements, and we have a stasis of the blood which may be active or passive, and manifests itself in heat, fever, pain, swelling, inflammation or passive congestion, effusion, etc., and which make up what is known as an 'attack of rheumatism.' The fever may result from the efforts of nature to get rid of the intruders, just as a householder will become hot in expelling from his premises a thief who is difficult to get rid of. Or, to use another simile, the attack of rheumatism is like the explosion of a gun. The charge in the gun is the morphology of rheumatic blood, and the cold is the pulling of the trigger. The charge may be latent in the gun for years, but it is there, with its potential energy ready to become actual from an exciting cause.

"Fibræmia.—In a nomenclature which was made before the present advance of knowledge, there is difficulty in making it fit to the new era. I shall not attempt to relieve this difficulty, but try to adapt the subject to the conventional names, as the object of this work is practical aid in treating diseases, no matter what they are called.

"Fibræmia is where the fibrin is in excess in filaments, skeins, curled massive fibres like strings, thrombi and emboli. These are in a more exaggerated condition and form than in consumption or rheumatism, and are not necessarily associated with the crystalline matters or gravel. Sometimes the fibres look like a scalp that has been taken from the head of a woman with long tresses of hair.

"Thrombosis is where masses of fibrin accrete and consolidate together, including or not the red corpuscles, white corpuscles, crystalline and pigmentary bodies, spores and mycelial filaments or vegetations, one or all.

"Embolism is where a thrombus has been caught or engaged in a blood vessel, and acts as a plug disturbing the circulation. When the embolus is made up of spores of mycoderma aceti or vinegar yeast, and is caught in the lung, it develops tubercle of the lungs, and so in other parts of the body. So senile gangrene of the extremities is caused by fibrinous clots plugging up an artery.

"Pre-embolic State.—As thrombi precede emboli, so they can be detected in the blood before the embolism, simply by the morphology of the blood. In this way, sudden deaths from embolism, specially in the puerperal state, can be averted, and this aid alone renders the microscope an invaluable assistant to the physician who is devoted to his profession."

2. HÆMIC OBSTRUCTION FROM THE CONDITION OF THE BLOOD VESSELS.

A. *Fatty Degeneration—Atheroma—Ulceration and Roughening.*—Atheroma is not always calcification. I have found it to be made up of crystals or plates of cholesterine in the aorta, thus proving a fatty degeneration caused by wrong feeding. In angina pectoris there are atheromatous deposits in the coronary arteries. May not the pain of angina pectoris come from a

¹ See Clinical Morphologies, E. Cutter.

colic or spasm of the partially paralyzed and fatty degenerated muscles, worn out by too much work in their weak state?

B. Trophopathic Increase of Heart Work.—In 1857, Dr. B. W. Richardson, of London, fed dogs on sugar chiefly, and found deposits in the blood stream and in the heart which he termed the essence of rheumatism.

1890. My son, Dr. J. A. Cutter, and myself have found embolism in swine dying from hog cholera. Out of seventy swine, sixty died; so that feeding on vinegary foods may be set down as a cause of increasing the work of the heart by causing the morphology of rheumatic blood-atheroma, embolism and thrombosis. - Food that produces carbonic acid, phosphuretted hydrogen, sulphuretted hydrogen or pure hydrogen causes a paralysis not only of the parts in contact with the gases of fermentation, but also by reflex, other organs, as for example the heart. The heart, paralyzed more or less completely, is overwhelmed, and fails to do its work. In America the newspapers term certain cases death from heart failure, showing, whether the cause of the failure is understood or not, that the great result is recognized. Gulping of wind from the stomach is often attended with death by the absorption of gases from the stomach. The mechanical pressure does not seem enough to cause instant death. Muscles partially paralyzed undergo fatty degeneration, which is a normal process in uterine subinvolution. Horses kept on high feed without proper exercise suffer muscular fatty degeneration, and become useless. Food used in excess containing carbo-hydrates or sugar produces fatty degeneration; so does phosphorus poisoning. A heart fed on starch and sugar is liable to fatty degeneration simply because the conversion of starch and sugar into fat is so easy chemically, and because of the paralyzing effects of carbonate acid gas in large excess. When a medical student, I once discharged a small stream of carbonic acid on the back of my hand. In a few minutes the spot was lead colored and insensible to prick and puncture. This occurred after the same stream had almost instantly killed a small snake in an empty glass jar.

Atheroma.—Although spoken of before, it should also have a place here, as it comes directly as a result of vegetable eating.

The morphology of rheumatism, fibræmia and consumption already alluded to, should come in here also, as they come directly from feeding of vegetable food that will ferment on it in a state of fermentation. The abnormal presence in blood of adhesive, sticky red blood corpuscles, massive fibrin filaments, single, aggregated in skeins, agglomerated in clots, free or mixed, including or not crystalline bodies, white blood or even red blood corpuscles, all are due to improper feeding as a general rule.

C. Gynec Causes of Heart Disease.—In my opinion, a large moiety of functional cardiac disturbance in women comes from uterine disease. Pains, distress, palpitation, are in my experience often in causal relations with the uterus. I have thought it was because the diseased uterus used up more force than normal, and called on the organs to make up the deficiency; hence the heart suffers often from loss of its own constitutional force in this way. The reason why I think so is because I have seen, for many years, hearts relieved by curing the uterine lesion. Indeed I feel so sure of this that I always advise a gynec exploration in such cases, feeling that even if this position is correct, there is a great gain in stopping the uses of nerve force that leaks from uterine disorders of place and substance. For example, Dr. Bowditch, of Boston, sent a woman to me in consumption, complaining greatly of severe pain over the precordium, combined with violent action. I suspected uterine reflex, and found complete anteversion, with hyperæsthesia of the uterus. A few iodoform capsules relieved the hyperæsthesia and replacement relieved the anteversion; with this relief went the cardiac symptoms. Suppose the woman has organic disease of the heart, the gynec disease aggravates it often. I am quite aware that chest specialists may be, and are, surprised at this statement, as it rather clashes with the conventional idea of specialism that the specialist must not go out of his domain; but as the gynec causes are great factors in cardiac disease, neither they nor trophopathics should be neglected by the specialist, unless he wants to be a nonentity and failure. It is high time that all specialists recognize the gynec reflex and systemic causes of special disease. Ten years ago I called attention to the connection of the uterus and the throat, and was laughed at for my pains; now the idea is adopted.

F. Postural.—In persons compelled to stand erect, as American street car drivers. (In Europe they are more humane, and allow these workers to sit; may it be so in America!) Here the work of the heart is done against a pressure of blood column high as the head. The effect is seen in the varicose veins of the legs, and must increase the work of the heart. Indeed, I have seen the reports of drivers falling over the dasher, run over and killed. It is very probable that the falls would not have occurred unless the heart had given out in a faint. When we sit, the height of the blood column is diminished by the length of the thigh.

In the horizontal position the blood pressure is taken off, and only the flow of the blood is carried on.

But if the legs are elevated, then the weight of the blood is added to the direction of the stream, and eases the heart greatly, forming a most im-

portant element in rest. I have known a man with hypertrophy and valvular lesion, who could not sleep in bed for thirty minutes at night, when placed on a resting chair, in which the feet were gradually brought higher than the head, to get in two days so much rest to his diseased heart that he slept all night in bed. This shows what a work it is for the heart to beat when the body occupies erect postures.

TREATMENT.

A. Conventional is to sedate or quiet the heart by medicine and local treatment, with no view of any positive cure, only to make the patient more comfortable, and smooth the pathway to the tomb. While this may be desirable, is it doing all that can be done? And is this conventional treatment on the right principle? I think not; and my opinion is based on the facts just given, and, as a person whose parents both died of heart disease suddenly, I give here what I believe to be:

B. The Rational Treatment of Heart Disease, by removing causes, which are:

a, hæmic; *b*, trophopathic; *c*, gynec; *d*, motional; *e*, emotional; *f*, postural; *g*, hereditary, and *h*, inflammatory; *i*, oiling the machine with medicine, and nature, who is all the time trying to cure all disease, will then arrest and cure. It is not rational, when the heart is growing large because of its increased work, to tone down and quiet the heart, unless at the same time measures are taken to stop the causes of that very increased work.

The writer has seen so many cases where stopping the causes has been followed by permanent cures that he thinks this is the rational way to treat such cases.

a. Hæmic causes, treatment same as b. Trophopathic. (a) Remove causes; (b) build up the system on food which does not have the alcoholic or vinegar fermentation; (c) use medicines as aids, helps, assistants, but not with the view that they alone can cure.

(a) *Remove Causes*; that is, the vinegar plants, the thrombi clots, the stickiness of the corpuscles, the fibrin filaments in excess, as to size, strength and skeins. This is done by stopping the fermenting food.

(b) *Build up the System* on food which does not undergo the alcoholic or vinegar fermentation. Beef is digested in the stomach; digests easiest, quickest and assimilates best; feeds all the tissues well, and can be lived on for years, as hundreds have proved. Unchopped beef answers in some cases, but in those who have been physiologically erring for many years, even the white fibrous tissues of the unchopped meat ferments like the vegetable food, and great advantages come from removing this connective tissue fiber. The American and Enterprise chopper are the best for this purpose. The muscle pulp

is moulded into cakes like fish-balls, broiled and seasoned with pepper, butter and salt, and eaten hot. (The cakes must not be moulded by hand, but with a knife and fork, so that the meat may not be too tightly pressed together; if it is, the meat will be livery and gelatinous, and apt to produce diarrhœa.) If properly prepared, it is palatable. No other food ere the fermentation ceases, except relishes of lemon juice and celery, the latter in small quantities, until the heart gets into better shape. The moment the blood stream is normal, that moment the heart improves. The moment the paralyzing gases are removed and kept away, that moment the heart improves obviously. By the autonomy of the heart, or by the *vis mediatrix naturæ*, the heart is on the road to restoration by first stopping the accumulation of the thrombi; second, by their solution in the stream of normal blood; third, by their consequent disappearance by absorption; fourth, as our bodies change all the time, our hearts change with them, of course, and by stopping the causes of deterioration, and furnishing a supply of healthy food in abundance, the new structures of the heart are laid down normally.

(c) *Medicines are aids* and help to oil the machinery. For example: Some cases will get well on diet alone, but medicines are usually an aid.

They may be classed as follows:

1. *Hot water* at the temperature of tea and coffee, to be drank one or two hours before meals and on retiring to bed, in quantities of from one-half to one pint at each drinking.

This hot water promotes peristalsis downwards, washes out the digestive organs soured with swill, vinegar, etc., then the blood and secretions; washes out the kidneys, liver and skin, cleanses the foul system, causes eructation of paralyzing gases, and can be used successfully when death seems imminent from heart failure. The use of pure spring water is advised, or distilled water, as being free from organic life, and more able to dissolve out the crystalline bodies that are formed in the blood of thrombosis.

2. A good vegetable tonic of fluid extracts, such as are not poisonous, to be taken before meals to tone up the digestive organs. A combination of several ingredients works well in many cases. Strychnia, digitalis and strophanthus can be used to good effect, but as indicated by the special case.

3. Some non-sugary pepsin and pancreatine after meals to help digest the food is an excellent idea.

4. Ammonia or alcohol sponge-baths night and morning help, as the skin is the largest gland in the body, and does a great amount of excreting work. It is vicarious in function with the digestive organs, lungs, kidneys, etc. It must be kept in good trim.

5. Rubbing, massage and passive exercise, as

riding and driving, are excellent aids to help the machine run better.

c. *Gynec.*—Make local examinations, and, having found out the difficulty, treat accordingly. In passing, I might say that I have found great advantage in the use of, 1, vaginal gelatine capsules filled with iodoform or iodol, and retained by absorbent cotton; 2, iodoform or iodol in uterine cavity to relieve the hyperæsthesia—the best of anything if used with care; indeed, I would not know how to do without them; so far aristol and other chemicals have not superseded iodoformis sedating powders; 3, platinum-plated uterine sound, also good to relieve lesions of place. My own pessaries, specially the stem.

d. *Motional.*—When going up stairs, the force thrown on to the heart is four to ten times as much as when locomotion on a level at the same rate of speed. Hence patients, in going up stairs, should count four between each step, or even ten; this gives the heart good usage. I asked a mill owner what would be the result if suddenly he turned four times the usual work on to his 250-horse power steam engine. He said it would be broken. And yet this is done to the heart all the while, and worse still, as the rate of speed is usually more in going up stairs than on a level.

e. *The Morale of the Patient Must be Cared for.*—He must understand why he does as he does; that if he transgresses, his sin will find him out in the heightened color of his urine, in the gas in the stomach, the heart symptoms re-appearing, and in a general fretful, fault-finding disposition with everything, which he will manifest. He should be cheerful and hopeful; make up his mind to get well, and then not worry, overwork or excite. Let the sympathetic nerves run unhindered. He should not live in his head. He should be very careful about exercise, remembering that the heart takes strength to get well, and to run the body in health. Tell him that it is work to live when sick, as it is more work to run a machine, a locomotive, pair of scissors, etc., when bearings need oiling, than when lubricated; hence, patients should take time and rest to get well. The physician should be in constant communication with the patient, and should often examine the blood, urine and feces to know how the system is running, and to correct any mistake as soon as detected. He should inform the patient that he is on plans that must be studied. The physician must believe, and make the patient believe, in the truth of the plans. He should not hunt to find something that is going to kill the patient, but should look for things to cure. Nor should they make up their mind that the patient is going to die.

f. *Postural.*—Place patient on a chair that has the motions of the leg and thigh in vertical planes. The feet can be put higher than the

head, and thus rest the heart. This acts well in practice.

g. *Heredity.*—These are best controlled by food plans for the benefit of posterity.

h. *Inflammatory.*—By posture, diet and depleting remedies, like veratrum.

Finally, the physician directs, the patient obeys, and nature effects the desired end—a healthy heart.

The Ariston, Broadway and 55th st., New York.

VOMITING OF PREGNANCY; ITS ETIOLOGY AND TREATMENT.

Read before the Allegheny County Medical Society, June 16, 1897.

BY F. BLUME, M.D.,
OF ALLEGHENY, PA.

Pregnancy, as a rule, is complicated with a variety of disorders, which, though in many instances causing much discomfort, are termed physiological as long as they are not associated with serious disturbances of the organism. Derangements of the gastro-intestinal canal, nausea and vomiting, to the consideration of which I invite your attention to-night, are such a regular occurrence during the early period of pregnancy that experienced women consider them as positive signs of conception.

The so-called morning sickness—nausea and vomiting early in the morning, or even after meals, during the first few months of gestation—have, in the large majority of cases, no effect either upon the course of pregnancy or upon the health of women. Although the ordinary morning sickness sometimes persists during the whole period of pregnancy, it remains endurable, causing the patient rather annoyance than injury. There are intermissions, either spontaneously or the consequence of some treatment; the digestive functions remain more or less normal, and the vitality of the patient is not essentially impaired. In some, fortunately very rare instances, however, nausea and vomiting become incessant and uncontrollable, the stomach rejects everything, the patient grows weaker till the most extreme degree of exhaustion is reached, and death from starvation threatens.

The onset of this grave form of the affection is gradual, and does not differ in character from the usual morning sickness. But soon the nausea becomes more intense, the vomiting more frequent. The ejected matter consists of food, mucus and bile. The appetite is more or less impaired or perverted; the thirst is excessive; constipation is more frequent than diarrhœa; the urine is scanty, concentrated, and contains albumen and casts. The pulse grows small and rapid, the temperature rises, and continued fever develops.

With the progress of the disease the condition of the patient becomes more and more alarming. The nausea is almost constant, adding greatly to the discomfort of the woman. The efforts at vomiting are accompanied by violent retching and pain; not the smallest amount of food or drink is retained by the rebellious stomach; the smell, even the thought of nourishment, or the slightest movement of the patient, induces an attack. The vomited matter is finally mixed with blood. The thirst is tormenting, the throat and mouth are dry, the tongue brownish, the breath fetid, the abdomen tympanitic. The consequences of this continued suffering soon become very pronounced by the marked alteration of the features, the extreme emaciation and the profound depression of the patient. Shortly before life ends, vomiting ceases and coma supervenes.

Cases of persistent vomiting, which terminate fatally, are certainly very rare. Even after the application of various methods of treatment has failed to influence the course of the disease, and while the induction of abortion was earnestly considered, the patients have recovered spontaneously, and have gone to full term, as I have seen in the only instance of this grave disorder which has come under my observation.

There is considerable diversity of opinion as to the causes which may incite hyperemesis, and, in spite of numerous theories and hypotheses, the etiology of this disorder is by no means clear. It is almost universally accepted to be a reflex neurosis originating in the uterus, and dependent either upon pregnancy alone or upon co-existent pathological conditions.

Pregnancy itself, the growing ovum, which acts as an irritant by the simple mechanical distension of the uterine cavity and its peritoneal covering, is in the first place to be mentioned as the most potent etiological factor.

Cases of multiple pregnancy and hydramnion, which present a disproportion between the passive distension and the active growth of the uterus, and which frequently are complicated with hyperemesis, confirm this view. Moreover, the induction of artificial abortion, our last resource in desperate cases, which almost immediately relieves the patient when done in time, is founded upon this theory of passive uterine distension, and strongly supports it.

Spontaneous death of the foetus, followed by immediate or remote abortion, is another remarkable fact in favor of this view.

A patient of mine, the mother of two children, was suffering from double laceration of the cervix, erosion and endometritis. She refused surgical treatment, and was relieved by repeated irrigations of the uterus with carbolyzed water, and by the application of tincture of iodine. She soon afterward conceived, and her pregnancy was complicated with the ordinary morning-

sickness from the second month to the beginning of the sixth, when the vomiting suddenly ceased. Two weeks thereafter she told me that she did no longer feel the movements of the foetus, that vomiting had ceased, and that she therefore believed the child was dead. Though I could not detect the fetal heart-sounds, I gave my opinion with reserve. Three and a half months later I delivered her of a dead foetus about five months old.

This case affords the most striking evidence of the discontinuance of reflex symptoms after the removal of the inciting cause. We have here pregnancy complicated with pathological conditions of the uterus, as double laceration of the cervix, ectropium, and probably a but partially cured endometritis, conditions which existed prior to conception and continued after the death of the foetus. But in spite of the persistence of these pathological conditions of the uterus, and of the retention of the dead foetus for almost four months, the vomiting disappeared with the death of the foetus, that is, with the cessation of the mechanical distension of the uterine cavity.

The influence of primary gravidity is demonstrated by the fact that hyperemesis in its grave forms is essentially an affection of primiparous women, and it is to be referred to the greater resistance of the virginal uterus.

Numerous other causes are given as etiological factors by different observers, among them: pathological conditions of the cervix, chronic metritis and endometritis, displacements of the uterus, inflammations of the pelvic peritoneum and connective tissue, ovarian neurosis, neurotic predisposition, hysteria, and lastly, diseases of the gastro-intestinal canal, especially gastric ulcer, chronic gastritis and constipation.

Morbid changes of the uterus are frequently the cause of reflex neuroses in non-pregnant women. The dependence of gastric disturbances upon the irritability of the uterine nerve fibers, due to flexion and version of the uterus, to an eroded and congested cervix, to metritis and endometritis, has, in many instances, evidently been proven. Relief has been obtained by the removal of the exciting cause, by the treatment of the uterine diseases after gastric medication had been tried again and again and had failed entirely.

Bearing in mind the physiological changes of the uterus during the pregnant state, its increased functional activity, the influence exerted by gestation upon the nervous system, and the relation between the neuroses and the disorders of the reproductive organs, so often conclusively proven in non-gravid women, we are compelled to acknowledge the various pathological conditions of the uterus as prominent etiological factors deserving our earnest attention. Cases are on record where the application of caustics to

the eroded cervix, scarification of the congested vaginal portion, dilatation of the cervical canal, correction of a flexion, have proven successful in stopping the vomiting, and thus demonstrated the connection between the uterine lesion and the reflex nerve action. In other instances, however, the result of the gynecological treatment has not been so satisfactory, either transitory or no relief has been obtained, and, as a consequence, the influence of the uterine disorders upon the gastric phenomena, their importance as the causative diseases has been questioned.

Undoubtedly it will be often found difficult to decide whether the symptoms result from physiological or pathological causes; whether they are due to distension of the uterus or to morbid changes in the sexual organs. All methods of treatment, artificial abortion excepted, may fail to relieve the patient, and she finally may get well by absolute rest and complete abstinence, to the surprise of her medical attendant.

Such cases are certainly rare, while, on the other hand, there is abundant clinical evidence of the effect of local treatment. Numerous women have been benefited by the treatment of the uterine lesion; the reflex symptoms have been mitigated or cured by the improvement of the causative disease, and the connection between both has thereby been confirmed.

Attention has been drawn to the importance of endometritis as an etiological factor by F. Veit,¹ who reported three cases of uncontrollable vomiting, where he was compelled to interrupt pregnancy, and where he found inflammatory processes in the decidua, serotina and vera. Veit believes that by his researches the dependence of hyperemesis upon endometritis is positively proven, as a rule the endometritis exists prior to gestation, the symptoms are but insignificant, become palpable, however, with the beginning of pregnancy, which frequently is interrupted by this complication. In many instances the endometritis decidua will be found to be the cause of the uncontrollable vomiting; the connection through sympathetic paths must be the same as between gastric disorders and endometritis in non-gravid women. The evidence of an anatomical base, he continues, renders a most careful examination of the uterus imperative, and, if the diagnosis of endometritis, which is very difficult before the removal of the ovum, can be made out, it may be of determining influence as regards the advisability of inducing abortion.

Quite recently E. H. Grandin,² discussing this subject in the New York Obstetrical Society, suggested ovarian neurosis, pressure on unusually hyperesthetic ovaries as a cause of hyperemesis. This view, he says, would be suggested by Dr. Coe's case, which showed that the physiolog-

ical vomiting of pregnancy could be palliated by teaching the patient to assume the genu-pectoral position before rising, and as often during the day as necessary. He would explain the vomiting of pregnancy, then, by the fact that during the early months the uterus lay low in the pelvis and pressed on the ovaries; at the third month, when the vomiting usually ceased, the uterus rose above the pelvic brim. In cases of pernicious vomiting it was possible the ovaries were either enlarged through disease or had become impacted between the pelvic brim and the lower uterine segment.

Grandin's theory, though it may be applicable to a given case, will probably not be favorably accepted. To-day the view is predominant that reflex neuroses may originate in the uterus, and not in the ovary. The removal of normal ovaries for the relief of reflex symptoms is at present restricted to exceptional cases, and it is believed that if a satisfactory result is obtained by the operation, this is due to the changes in the condition of the uterus, to the artificial induction of the menopause, resulting from oöphorectomy. Clinical evidence supports this view.

Grandin's explanation, however, may prove valuable in so far as to induce us to carefully examine the ovaries in cases of hyperemesis. Pro-lapsed ovaries are by no means a rare affection, but it remains to be demonstrated whether pressure exerted upon them by the enlarged uterus stands in causal relation to gastric disturbances.

Nervous disposition and hysteria, so frequently met with among women of the better classes, add greatly to the discomfort of pregnancy, and, though there are certainly many exceptions, must be considered as prominent predisposing factors of the graver forms of vomiting.

The importance of diseases of the gastro-intestinal canal, especially of gastric ulcers, is emphasized by various authors. According to Horwitz³ "hyperemesis develops in some cases complicated with more or less pathological changes of the stomach and of the intestines. The greater the disturbance in the alimentary canal the easier the ordinary vomiting takes on the character of the uncontrollable form."

The diagnosis of vomiting of pregnancy is by no means as easy as one might think at first sight. While the dependence of this disorder upon the pregnant state may often be determined without much difficulty, cases—especially of the graver forms—may present themselves where this will be found impossible, and where the diagnosis, therefore, must remain doubtful. Faggard⁴ directs our attention to the fact "that so few cases of pernicious vomiting are recorded in German medical literature that the existence of this affection is even questioned." Carl Braun, in a

³ Praktischer Arzt, 1882, p. 261.

⁴ American System of Obstetrics, Vol. I, p. 411, 415.

fabulous experience of over one hundred and fifty thousand obstetrical cases, has never observed a single fatal termination. On the other hand, Robert Barnes has himself seen 9 fatal cases. McClintock collected close on 50 cases, and O. W. Doe 48 cases with 18 deaths occurring within the last fifteen years, and registered in American and English journals. Gueniot records 118 cases with 46 deaths.

It is not at all improbable, Faggard continues, that the difference of opinion as to the frequency of this disorder between the Germans on the one hand, and the American, French and English observers on the other, depends, in a large measure, upon the difference in diagnostic criteria insisted upon by the respective schools. In the majority of the fatal cases of alleged hyperemesis due to pregnancy reported by American, French and English observers, there is a notable absence of reliable records of post-mortem examinations. In the few cases collected by the Germans, on the other hand, the diagnosis during life has almost invariably been confirmed or negatived by exact investigation of the dead body. Horocks pertinently remarks: "Where there has been no post-mortem examination in a fatal case of vomiting, I do not think that one is entitled to say that pregnancy caused the fatal vomiting. It may have been the cause, and the only cause, or it may have been an aggravation of some other cause, or it may have had nothing to do with it. Skepticism as to the alleged frequency of this disorder, in the present state of our knowledge, is accordingly eminently in order."

According to Gueniot,⁵ three distinct factors are to be taken into consideration in making the diagnosis of vomiting of pregnancy: 1. The diagnosis of pregnancy; 2. The diagnosis of the adjuvant or determining cause of the vomiting; 3. The differential diagnosis between obstinate vomiting due to pregnancy, and that due to other causes independent of gestation.

It is both interesting and instructive to learn that errors in diagnosis have been made even by eminent clinicians. Thus Faggard⁶ tells us that Trousseau once diagnosed uncontrollable vomiting, and induced abortion, in a case in which the autopsy revealed cancer of the stomach. Beau erred in diagnosis in a case in which the post-mortem examination showed tubercular meningitis as the probable cause of the vomiting, and Cazeaux narrates the history of a fatal case of alleged hyperemesis of pregnancy where the autopsy disclosed tubercular peritonitis and the absence of pregnancy.

But a mistake in diagnosis is possible even in the other direction—that is, pregnancy may be denied by the patient or not be expected by the physician, and thus be overlooked, as shown in

a case recently reported by A. H. Buckmaster.⁷ The patient, a governess in a respectable family, was supposed to be suffering from vomiting due to ulcer of the stomach, and was under treatment two months, when she died. In making the autopsy a five months' fetus was found, but no ulcer whatever, nothing to account for death except the uncontrollable vomiting of pregnancy.

These cases need no comment. I have cited them to demonstrate both the difficulty and the importance of an accurate diagnosis.

It is generally stated that the prognosis of hyperemesis is bad, but this, apparently, is by no means correct. As Faggard justly remarks, "it is doubtful whether an authentic fatal case of this kind is recorded. Such cases have never been seen by observers of the largest experience."

Even the graver forms of this disease yield, as a rule, to rational treatment, unless they are complicated by serious pathological conditions which of themselves render recovery impossible. Pregnancy may aggravate such cases, and perhaps hasten death, but it must be admitted that there exists no causative relation between gestation and the lethal issue.

A great variety of remedies—still increasing in number every year—have been recommended by different writers. These remedies have proven satisfactory in some cases, but failed entirely in others. This uncertainty of the various methods of treatment, the often but little annoyance caused by the milder forms of vomiting, and the experience that in many instances spontaneous cures occur, have led to the view that interference is not required unless the case presents a more serious aspect. Such advice given in text-books is, at first sight, surprising. Even in mild cases of gastric trouble a careful examination is indicated, and should be insisted upon by the medical attendant, to determine the cause of the disorder, its dependence upon physiological or pathological conditions. Are the generative organs found to be normal? Are there no indications of diseases of other vital organs, especially of the stomach? Is the effect of the vomiting upon the general health but insignificant? It may then be decided whether it be a wise plan to irritate the stomach by various drugs, which, as known from experience, are of so limited value in this reflex affection, or to desist from treatment. It is in this sense, I take it, that such advice has been given, and it is under these circumstances that it deserves recommendation. Nevertheless, such statements in text-books are misleading, fortunately, but to the superficial reader.

While mild cases of vomiting do well without treatment, diet and regulation of the bowels are usually sufficient to render the gastric disturbances tolerable, but the persistent vomiting demands our earnest attention.

⁵ Faggard, *American System of Obstetrics*, Vol. i, p. 416.

⁶ Loc. cit.

⁷ *American Journal of Obstetrics*, 1890, p. 1381.

Hyperemesis, a reflex neurosis, is either due to physiological changes in the uterus, distension by the growing ovum, or to pathological conditions complicating pregnancy. If we exclude co-existent diseases of the stomach, which will be considered later on, it must seem plausible that the treatment should be directed against the causes and not against the symptoms of the gastric disorder; that is, against the uterus, and not against the stomach. The stomach is not the diseased organ. Nausea and vomiting of pregnancy are only the symptoms of some functional disturbance of the nervous system, originating in the uterus, like the nausea and vomiting of sea-sickness, an analagous disease, dependent upon the motion of the ship. For this reason gastric medication must fail to favorably influence hyperemesis; for this reason none of the innumerable remedies recommended are found to be reliable—some of them are worse than useless.

There are three classes of cases, however, which sometimes may be relieved by the administration of drugs, viz.: 1. Women who, prior to gestation, have been afflicted with diseases of the stomach, as chronic gastritis and gastric ulcer; 2. Women of an unusual nervous irritability; and 3. Hysterical women.

In cases of the first category sub-nitrate of bismuth, bicarbonate of sodium, Carlsbad water, oxalate of cerium, the tincture of nux vomica, etc., may be tried and may sometimes be found of decided value, while the nervines and sedatives may give relief to nervous and hysterical women. Opium and its preparations, the bromides and chloral, either administered by the mouth, by the rectum, or hypodermically, as the circumstances require, are the medicinal agents which have the best reputation, and which, in these cases, sometimes successfully depress the reflex irritability, and thus alleviate the symptoms. Blisters, the application of chloroform, ether, and of the faradic current to the epigastrium, of the ice-bag to the dorso-lumbar region have been tried and have afforded relief in some instances.

The resort to local treatment is indicated in all those cases in which a morbid condition of the uterus has been made out. Retroflexion and retroversion are to be corrected, and, if necessary, the uterus is to be retained in position by a suitable pessary. A congested vaginal portion may be relieved by scarifications, while the application of carbolic acid, or of a 10 per cent. solution of nitrate of silver to the eroded cervix will often prove successful in mitigating the distressing symptoms. Faggard⁸ states that in Vienna a 10 per cent. solution of nitrate of silver is employed in all cases of severe vomiting, irrespective of the condition of the vaginal portion. "The weight of testimony in favor of this simple pro-

cedure, collected from innumerable sources, is so great as to make its employment absolutely obligatory before resorting to more radical methods."

Dilatation of the cervix—Copeman's method—has proven successful according to some writers, while others report negative results. In the only case of severe vomiting which I have observed it had a most remarkable effect. The nausea disappeared instantly, but only for a few hours. The method was again applied, but no result was obtained the second time.

Horwitz⁹ recommends that in the severer cases of vomiting the patient should be placed at rest in bed in the horizontal position, that the room be darkened, and that, if the stomach rejects everything, rectal alimentation should be resorted to. Crushed ice to quench the thirst is allowable. I can fully endorse this plan.

When these various methods have failed, when the vomiting actually is uncontrollable and seriously endangers the patient's life, the induction of abortion or premature labor is indicated, and will, if done in time, to a certainty save the woman.

CONGRESS FOR THE STUDY OF TUBERCULOSIS.—On July 17, this Congress was inaugurated by a visit to Professor Lannelongue's wards at the Hôpital Trousseau, where the cases treated according to the new chloride of zinc method were passed in review. Later, the first meeting was held at the Faculty of Medicine, under the Presidency of the veteran Villemin. About 400 members were present to listen to addresses by Professors Verneuil, Grancher and Arloing. The latter inquirer gave experimental proof of the inefficiency in the laboratory of Koch's tuberculin. Meetings were held on the 28th, 29th, 30th and 31st, and visits were paid to Professor Verneuil's wards at the Hotel Dieu, where patients treated by injections of iodoformed ether were presented; to the Val-de-Grâce Military Hospital, to see the cases treated by creasoted oil; and to the Institut Pasteur. A grand banquet took place on Thursday evening. In connection with this subject, the *Progrès Médical* revives the question of the disinfection of railway carriages employed for the conveyance of phthisical visitors to the southern health resorts. Prausnitz is quoted as having examined the dust of *coupés* on the express train doing the service between Berlin and Meran—a route much frequented by consumptives. He inoculated this dust into guinea pigs according to the serial method of Cornet, and found that two out of five *coupés* contained the tuberculous bacillus. The journal above mentioned urges the Paris-Lyon-Méditerranée Compagnie to provide—at least for the better class of travelers—antiseptic spittoons.—*Boston Med. and Surg. Journal*.

BY-LAW IV.—THE PUBLICATION OF PAPERS AND
REPORTS.

No report or other paper shall be entitled to publication in the
volume for the year in which it shall be presented to the Associa-
tion, unless it be placed in the hands of the Board of Trustees on or
before the first day of July. It must also be so prepared as to re-
quire no material alteration or addition at the hands of its author.
Authors of papers are required to return their proofs within two
weeks after their reception; otherwise they will be passed over and
omitted from the volume.

Every paper received by this Association and ordered to be
published, and all plates or other means of illustration, shall be
considered the exclusive property of the Association, and shall be
published and sold for the exclusive benefit of the Association.

The Board of Trustees shall have full discretionary power to
omit from the published *Transactions*, in part or in whole, any pa-
per that may be referred to it by the Association, or either of the
Sections, unless specially instructed to the contrary by vote of the
Association.

THE GERMS OF TYPHOID FEVER.

The lectures delivered at the post-graduate
course at Toronto last winter, have reached us
in pamphlet form. Among them is one by PROF.
VICTOR C. VAUGHAN under the above caption.
After reviewing the work which has been done
by various investigators as to the presence of the
KOCH-EBERTH germ in typhoid fever, and the
attempts to inoculate lower animals with it, he
sums up as follows:

1. A germ giving the tests supposed to be
characteristic of the EBERTH germ is found in-
variably in the bodies of those dead from typhoid
fever.
2. It has been isolated and grown in pure
cultures.
3. All attempts to induce typhoid fever in the
lower animals by inoculation with this germ
have so far been without success.
4. Experiments show not only that the germ
fails to multiply in the lower animals, but that,
when introduced by inoculation, it soon dies.

The failure of the inoculation experiments
may be due to insusceptibility on the part of the
lower animals, or the germ employed may not be
the cause of typhoid fever.

HUGUENIN, as quoted by MURCHISON, says
that enteric fever with characteristic intestinal
lesions is by no means uncommon among cattle
in Switzerland. In 1882, BRAUTLECHT inocu-
lated rabbits with germs from water supposed to
be the cause of a typhoid epidemic, and pro-
duced in them a wasting febrile disorder lasting
from two to eight weeks, with the post-mortem
evidences of severe catarrh of the small intestine.
The intestinal walls were thickened and friable,
the mucous membrane swollen, yellowish, and
reticulated; ulceration was present in some
cases, but was generally confined to individual
glands. There was marked enlargement and
coloration of the spleen and mesenteric glands.
In 1885, SEMMER reported typhoid fever in three
dogs and a horse, in which the lesions were well
marked. From this it would appear that the
disease probably occurs in the lower animals, and
the failure of the inoculation experiments can-
not be explained by assuming the contrary.

VAUGHAN'S own work on the subject is of
value, particularly as to the sufficiency of the
identification of the KOCH-EBERTH bacillus.
The KOCH-EBERTH germ is said to be identified
by its resistance to stains and by its invisible
growth on potato.

Two germs which VAUGHAN has frequently
found in drinking water, and which he desig-
nates as bacillus A, and bacillus B, are under
ordinary circumstances very readily distinguished
from the KOCH-EBERTH germ. But VAUGHAN
grew these germs on healthy human spleen, at
temperatures of 39° C. to 40° C. (102.2° F. to 104°
F.), and made cultures from them from time to
time. After seven days bacillus A was so modi-
fied that its growth on potato could not be dis-
tinguished from that of the KOCH-EBERTH germ.
And after fourteen days, it did not take stains
even as deeply as the KOCH-EBERTH germ. Sim-
ilar results were obtained from bacillus B.

RODET and ROUX in 1890 found that the bacte-
rium coli commune when cultivated at a temper-
ature of 44° C. to 46° C. acquired a close resem-
blance to EBERTH'S germ.

VAUGHAN concludes that we must abandon
the belief that typhoid fever is due at all times to
one and the same germ which can be recognized
by certain peculiarities in staining or in manner
of growth.

Whether this conclusion will be generally ad-

mitted or not, we must agree that the experiments of VAUGHAN and those of RÖDER and ROUX show that the characteristics by which it has been sought to recognize the Koch-Eberth germ, can be acquired by some other germs by exposure to continuous high temperature, that is to say, to fever temperature. These experiments do not show, however, that the germ originally described by EBERTH was not the cause of typhoid fever, although they throw doubt, in fact almost render valueless, observations relating to the germ, which have included as their means of recognition its peculiar growth on potato and its relation to staining agents.

It would seem also that it has not yet been shown beyond doubt that the lower animals are the subject of true enteric fever.

PANCREATIC DIGESTION OF FATS.

Last week we referred to the work of GAD and RACHFORD on the formation of spontaneous emulsions. They found that if a drop of oil containing $5\frac{1}{2}$ per cent. of fatty acid was dropped upon a $\frac{1}{4}$ per cent. sodium carbonate solution, a spontaneous emulsion was formed. Using this method in the investigation of the pancreatic digestion of fats, RACHFORD discovered some very interesting and valuable facts. Discouraged by HEIDENHAIN'S attempts to make permanent pancreatic fistulæ in dogs, he made use of temporary fistulæ in rabbits, in this way always securing fresh juice for his experiments. The portion of the duodenum containing the end of the pancreatic duct was resected, brought to the surface of the abdomen, and the pure juice obtained through a glass canula inserted into the open end of the duct. Taking the pancreatic juice so obtained, it was shaken up with neutral olive oil for a moment, and then the two allowed to separate. A drop from the supernatant oil was then pipetted off and dropped upon a $\frac{1}{4}$ per cent. solution of sodium carbonate. This operation was repeated every three minutes until a perfect spontaneous emulsion was formed. As an average of his experiments, he found that about twenty minutes was required to form the perfect emulsion under these circumstances; or, in other words, the juice would produce $5\frac{1}{2}$ per cent. of fatty acid in the oil in twenty minutes. These experiments were conducted at the ordinary temperature of

the room, 18° C. (64.4° F.). When the mixture of the oil and juice was kept at the temperature of the body, the fat-splitting activity of the juice was doubled, and the $5\frac{1}{2}$ per cent. of fatty acid was formed in about ten minutes. The emulsions formed in this way had all the peculiarities of the emulsions formed with neutral oil, to which a definite amount of fatty acid had been added, and sodium carbonate solution, to which we referred last week. The most important feature of his experiments, perhaps, was his determination of the influence which the other digestive agents had upon the fat-splitting properties of the pancreatic juice. Representing the activity of the juice at room temperature by 20, the addition of dilute hydrochloric acid was found to reduce this activity to 13, while the addition of the principal constituent of the bile, viz., the glycocholate of soda, increased it to 44. When the glycocholate of soda and hydrochloric acid were both added, the activity was still further increased, being represented by 56. That the other ingredients of the bile were not unimportant in this connection was shown by the fact that the juice and bile alone had an activity of 64. The greatest effect, however, was obtained by a mixture of pancreatic juice, bile and hydrochloric acid, the activity of the mixture being 80, or four times that of the pancreatic juice alone.

RACHFORD'S experiments show very clearly that the bile does not assist in the emulsification of fats as has been so long taught, but, on the contrary, directly interferes with the emulsification, while it does assist powerfully in decomposing the fats into glycerine and fatty acids.

It has been the custom of late to study the digestive ferments separately, in order to obtain so-called accurate information, but these experiments certainly indicate that the combined action of these ferments may give strikingly different results from what their separate actions would indicate.

BEQUESTS TO HOSPITALS.—Under wills recently probated the following institutions obtain liberal gifts: The Grady Memorial Hospital, of Atlanta, Ga., receives \$7,500 from the estate of the late William A. Moore, and the Rhode Island Hospital, at Providence, \$80,000, as a legacy of the late J. Wilson Smith.

THE COLLAPSE OF FATHER MALLINGER.

It is reported that FATHER MALLINGER, the alleged faith-healing priest of Troy Hill, Pittsburg, has been enabled to lay up earthly treasure to the amount of \$3,000,000. The Pittsburg papers have apparently found a satisfactory explanation for the Father's erratic course in the fact that he has a good knowledge of the healing art, having regularly graduated in medicine in Germany, and having been a country practitioner before the time of his entering holy orders. He gives medicines in many cases and the patients are bidden to send to him to have them renewed. The nature of his materia medica has not been made known.

In regard to the *fiasco* which occurred on St. Anthony's day, there can be little doubt that lives were lost rather than saved, as the unfortunate pilgrims to Mount Troy were led to believe and hope would be the case. Several deaths were reported as having occurred very soon after that day, probably caused by the excitement and resultant depression naturally following the pilgrimages of many from a distance, and undue mental and physical strain. Many of these hopeful pilgrims were of the poorest classes, and spent their little all in this final grand effort to obtain a cure, so that many of them must have been made worse by their journeyings, even if they did not die by the way. The newspaper reporters, who did so much to raise the senseless and sensational expectations of the unfortunates, have of late been engaged in ferreting out the alleged marvelous "cures" and in demonstrating that most of the cured persons "are still far from being well."

ORTHOPÆDIC SURGERY DEFINED.

In the twenty-third annual report of the New York Orthopædic Dispensary, DR. NEWTON M. SHAFFER offers the following comprehensive definition of the province of orthopædic surgery: "It is that department of surgery which includes the prevention, the mechanical treatment and the operative treatment of chronic or progressive deformities, for the proper treatment of which special forms of apparatus or special mechanical dressings are necessary." The underlying thought which dictates the above definition implies that the fully qualified orthopædist shall be prepared to do surgical operations in that range

of cases where special mechanical measures must be employed after those operations, but the operative treatment must stand in a position secondary to the mechanical; and the conservative element is seen in the union of the two treatments. Those deformities which general surgery is competent to relieve at once, or without the intervention of mechanico-therapy, are excepted under the foregoing definition.

MARION-SIMS MEDICAL COLLEGE IS IN LINE.

—At a recent meeting of the Faculty of the Marion-Sims College of Medicine, the Dean, Dr. Young H. Bond, introduced the following resolutions, which were unanimously adopted:

WHEREAS, The position taken by this college upon the two questions of Medical Legislation and Medical Education, has been intentionally confounded, and

WHEREAS, Notwithstanding the fact that, at the last meeting of the Missouri State Medical Association, the report on Medical Education offered by Dr. McAlester, and having as its central idea a three years' graded course of lectures, was, on motion of your Dean, with the aid of the votes of all the members of this Faculty then present, adopted, it has been sought to have it appear that this college is not favorable to higher Medical Education. Therefore, to the end that our position upon the question of Medical Education be clearly understood, be it

Resolved, That after the session of 1891-'92, the Marion-Sims College of Medicine will exact as a condition to graduation in medicine, of all its students who may not have previously matriculated, attendance upon a graded course of lectures extending over three years. And be it further

Resolved, That our position upon the question of Medical Education does not in the least abate or compromise our objection to what we regard as the attempted enactment of unjust, inefficient and class Medical Legislation, and that this Faculty favors an Examining Board as the fair and rational solution of the problem of Medical Legislation and Medical Education as well.

MARINE-HOSPITAL SERVICE.—A board of surgeons for the examination of candidates for admission into the Marine-Hospital Service will be convened at the United States Marine-Hospital, St. Louis, Mo., October 12, 1891.

Candidates for examination should make application to the Surgeon-General U. S. Marine-Hospital Service, Washington, D. C., as early as practicable, and should enclose testimonials from at least two reputable citizens, preferably physicians, as to their professional and moral char-

acter. No person will be considered eligible for examination, whose age is less than 21, or more than 30 years, or who suffers from any physical defect which would be liable to impair his efficiency or incapacitate him from duty. The candidate must be a graduate of a medical college of good standing, as evidence of which his diploma should be submitted to the board.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

The impression has for some time been prevalent, that the various private hospitals in the city have been rather too much given to the practice of transferring dying patients to Bellevue Hospital, with a view to keeping down their own death-rate to as low a point as possible, without regard to the bad showing that the records of Bellevue would consequently make. A case in point was published in the newspapers last spring, where an old negro was found lying in the street in an unconscious condition on the lower part of University Place. An ambulance was summoned from St. Vincent's Hospital, which was quite near at hand; but the ambulance surgeon, after examining the man, and finding him to be in a dying condition, took him to Bellevue Hospital, more than a mile and a half distant, instead of to his own hospital.

In commenting on this case, the warden of Bellevue remarked that it was only one out of many instances of inhumanity on the part of the private hospitals for the purpose of keeping down their death-rates. It was the plain duty of the ambulance surgeon, he said, to take the patient to the nearest hospital, and although he was very likely past medical aid, the long ride on the rough pavement to Bellevue certainly did not improve his chances of living. "We are powerless," continued the warden, "because most of the hospitals are classed as private, although they receive money from the city. These hospitals unload everything at Bellevue that looks like death, and the death-rate here makes it look like a slaughter house. After dark, every night, there is a string of ambulances from all the hospitals in town passing through the gates of Bellevue, carrying dying patients. These have been treated at the hospitals until there was no chance left of curing the diseases from which they were suffering, and then the order was given to take them to the dead house—meaning Bellevue. The doctors at the other hospitals laugh at us. Bellevue is a charity hospital belonging to the city, and we have to take all patients who are unable to pay their board."

If, however, we are to believe the report of a committee appointed by the Grand Jury to examine the condition of the ambulance service in the city and to make recommendations for improving its efficiency, which has just been made to the Court of General Sessions, it is not

true that the private hospitals are in the habit of transferring patients to Bellevue for the purpose of diminishing their death-rates. Such transfers as are made, the committee is satisfied, are proper and necessary. It is certainly to be hoped that this is really the case. At all events, this report, which has been prepared by four gentlemen of intelligence and position, contains much that is interesting and valuable.

In regard to the private hospitals which have an ambulance department, they state that they found the ambulance equipment and service such as called for approval. The ambulance surgeons are all graduates in medicine, and no one is detailed for this service until after he has had six months' active duty in the hospital wards. These private hospitals are the New York Hospital, the Chambers Street Branch of the New York, the Roosevelt, St. Vincent's, the Presbyterian and the Manhattan, and they have altogether twelve ambulances. During the year 1890 St. Vincent's had 1,930 ambulance calls; the Manhattan, 567; the Presbyterian, 1,202; the Roosevelt, 1,530; the New York, 1,321; and the Chambers Street, 2,678. The public hospitals with ambulance service are Bellevue, its down-town branch, the Gouverneur, and its up-town branch, the Harlem; and they maintain ten ambulances. During the year 1890 Bellevue Hospital had 4,246 ambulance calls; the Gouverneur, 2,374; and the Harlem, 1,225.

In its report the committee urges the Commissioners of Charities and Correction to establish as promptly as possible a hospital at Fordham, in the portion of the city which was annexed from Westchester County, which has for some time been in contemplation, as it is highly desirable that the districts beyond the Harlem River should be thus provided. It also recommends the early establishment of a hospital, with ambulance service, on the west side of the city, at some point about midway between the Roosevelt Hospital, at 59th Street, and the Manhattan, at 131st Street. There was formerly a public reception hospital at 99th Street, but this was given up some time ago, and the population is increasing very rapidly in this quarter.

In criticising the present faulty system of sending calls for ambulances, the committee does not hesitate to pronounce it positively discreditable that the city is still without a comprehensive system of signal-boxes or stations distributed through the streets in large numbers, so that an ambulance can be summoned with the smallest possible delay. "While we find very much to commend regarding the response by all hospitals to ambulance calls upon them," says the report, "we are compelled to criticise very generally the present notification to the hospitals of the necessity for an ambulance at a location where some one may be suffering." Consequently, the committee urges upon the Police Commissioners the importance of at once selecting the most approved and perfect system available for rapid communication with station houses both for ambulance service and for police purposes; and it also asks the Board of Estimate and Apportionment to at once appropriate the money required for this object. In conclusion, it expresses the fear that the cable roads which are now being laid in many of the principal thoroughfares of the city will be likely

to cause an unusually large number of street accidents, especially during the first year that they are in use; and on this account particularly the committee feel that it is highly important that the various recommendations embodied in their report should receive the prompt attention of the proper authorities.

It having been very gratuitously announced by one of the morning papers that Dr. Louis A. Sayre had been obliged on account of ill health to resign his position as Professor of Orthopædic Surgery in Bellevue Hospital Medical College (which he has held ever since the school was founded), and also to retire from practice, the doctor has been obliged to come out in a letter in which he states that neither of these assertions are true, and that while he was confined to the house for a number of months by a very severe attack of rheumatism, he is now sufficiently well to attend to practice and to drive in the Park every fair day. Long indeed may the illustrious and noble-hearted surgeon be spared to the profession and to the city which his honored name has so highly adorned!

Miss Waterbury, a wealthy maiden lady who recently died in Brooklyn, has set an example worthy of emulation by leaving among her bequests the sum of \$5,000 to her old and faithful family physician, and \$3,000 to his daughter.

There has just sailed from this port, with a fair American bride, a real Egyptian Pasha, who is at the same time an English physician of distinction. His name is Crookshank, and while yet but a medical student he served with honor in the medical corps of the German army during the Franco-Prussian war. Later he was a surgeon in the Turko-Russian and Servian wars, and in 1883, when the cholera was raging in Egypt he went to Cairo, where his eminent services attracted the personal attention of the Khedive, who made him a Pasha and appointed him Director-General of Egyptian prisons, a position which he still holds.

P. B. P.

Editor Jour. Am. Med. Assoc'n:—The college announcements of this summer prove that the discussions in past years regarding the improvement of medical education have had considerable effect. The usual directions in which changes for the better are made are in requiring more exact proofs of a good preliminary education, and in increasing the number of courses of college study. There is yet another simple method of securing increased efficiency in the graduates by adding one or two years to the minimum age for graduation. It would not be much of a hardship if it were the rule that the degree of M.D. should not be conferred on a student less than twenty-three years old. Most students are of this age when they graduate. This age is early enough to undertake the responsible duties of a medical practitioner, and the desiderated maturity of intellect, and preparatory literary education might be more certainly attained if students should not be allowed to begin a career of serious investigation when they are mere boys.

Premature Rupture of Membranes not Followed by Miscarriage.

Editor Jour. Am. Med. Assoc'n:—I have just read Dr. Johnson's article in THE JOURNAL on "Premature Rupture of Membranes not Followed by Miscarriage," and would be glad to report two similar cases—not for the purpose of reporting them only, but to offer a different diagnosis, inasmuch as I think his diagnosis is misleading to the younger members of the profession. My first case, a multipara, white, aged 30 years, pregnancy advanced to the sixth month, had a flow of quite a quantity of fluid which I at the time supposed was amniotic, but the case went on to term without any further difficulty, and I concluded that I was wrong. Shortly after I met with another case, also a multipara, white, aged 28 years; pregnancy advanced to the seventh month. Here again was a large flow of fluid, resembling amniotic fluid, but nothing further developed, and the woman went on to term and was delivered of a healthy child.

Here, now, are two cases which the young practitioner might consider as premature rupture of the membranes, but in reality were nothing more than hydrorrhœa.

For a discussion of the subject I would refer the reader to Cyclopædia of Obstetrics and Gynecology. By Charpentier. Vol. II, page 218. Also to the valuable works of Lusk and Playfair.

S. P. DEAHOFE, M.D.

Mineral Point, Wis., August 17, 1891.

BOOK REVIEWS.

THE PATHOLOGY, DIAGNOSIS AND TREATMENT OF INTRA-CRANIAL GROWTHS. By PHILIP COOMBS KNAPP, A.M., M.D. Boston: Rockwell & Churchill. 1891. 8vo., cloth, pp. 161.

This book is the essay to which was awarded the Fiske Fund prize at the annual meeting of the Rhode Island Medical Society, held at Providence, June 12, 1890.

The essay is based on the records of forty cases with necropsies, thirty-eight of which were patients at the Boston City Hospital.

There is a chapter each on Ætiology, Pathological Anatomy, General Symptomatology, Special Symptomatology, Diagnosis, Course Duration and Prognosis, and Treatment. There is a table of cases of removal of intra-cranial growths, and a list of references.

Examination of the book shows that as a record and commentary on the forty cases, it fulfils its mission, but it can by no means take the place of a systematic treatise on the subject. It cannot be favorably mentioned in comparison with Bramwell on Intra-Cranial Tumors, on account of its lack of system, and of thoroughness. It fails to mention the records of many accessible hospital reports, and the following statement is made on page 25: "In America they" (*parasitic cysts*) "are rare, and the hos-

pital records show very few cases of hydatid cysts anywhere in the body, and none in the brain." The author will find an "American" case of hydatids of the brain in the report of the Marine-Hospital Service for 1883, p. 220, and another in the same series of reports for the year 1888, p. 324. There are recorded in these reports 571,528 cases of disease, from 1873 up to 1890, and the total deaths recorded were 7,367, and the number of necropsies 1881 to 1890 were 1,913—out of this total the reports show but seventeen cases of intra-cranial tumors; six of the seventeen were gummata. These figures are given to indicate a source of information too frequently overlooked by medical statisticians, and to correct an error of the author. The reports of several American hospitals for the insane might also be consulted with advantage.

We commend the book, as a generally careful piece of work, and as giving in small space a fair review of the subject, and as such it will be welcome to the table of every neurologist and general surgeon.

A MANUAL OF MODERN SURGERY. AN EXPOSITION OF THE ACCEPTED DOCTRINES AND APPROVED OPERATIVE PROCEDURES OF THE PRESENT TIME, for the Use of Students and Practitioners. By JOHN B. ROBERTS, A.M., M.D., Professor of Surgery in the Woman's Medical College of Pennsylvania; Professor of Anatomy and Surgery in the Philadelphia Polyclinic; Lecturer in Anatomy in the University of Pennsylvania. With 501 Illustrations. Philadelphia: Lea Brothers & Co. 1890.

It is difficult to conceive in what manner more of practical instruction could be conveyed in the brief space of 770 pages, than is presented in this practical manual by Professor Roberts. A review of Part First, which is devoted to general surgery and pathology and the principles of surgery, clearly indicates that upon the essential points with reference to inflammatory processes, diseases of the blood, the modes of repair and the treatment of wounds, as well as in the details of operative surgery, the latest views upon these important subjects are well represented. Part Second of the volume contains some fifteen chapters which treat upon the surgery of special structures. The one upon diseases and injuries of the brain and spinal cord will well repay repeated perusal. So also of the one upon surgical diseases of the abdomen and pelvis. The proper methods of treating injuries of every sort are well described. By text and by ample illustrations selected from a variety of authors, as well as from original drawings, the methods of operating are clearly set forth, and its suggestions will be helpful both to students and practitioners. Much of value will be found relating to all the special departments of surgery, so that not only to students and to

general practitioners, but as well to specialists, this work commends itself.

As a contribution to American medical literature it does credit to its author, while to the American profession, with which Dr. Roberts stands so pleasantly related, it proffers another valuable American contribution.

In its publication it bears evidence of the same good taste and liberal expenditure which has through long years been characteristic of the house from which it emanates.

TEXT-BOOK OF HYGIENE. A Comprehensive Treatise on the Principles and Practice of Preventive Medicine from an American Standpoint. By GEORGE H. ROHÉ, M.D., Professor of Obstetrics and Hygiene in the College of Physicians and Surgeons, Baltimore; Director of the Maryland Maternité; Member of American Public Health Association, etc. Second Edition, thoroughly Revised and largely Rewritten, with many Illustrations and valuable Tables. Philadelphia and London: F. A. Davis, Publishers. 1890.

The appreciation of this work is best shown by the fact that a second edition is so soon in demand. An opportunity is thus afforded for Professor Rohé to incorporate much valuable matter which has been gathered from the fields of preventive medicine, since the issue of the first edition. The second edition bears evidence of a very thorough revision. Over a hundred pages have been added to the text.

The first five chapters are devoted to the subjects of air, water, food, soil and sewage. The construction of houses and hospitals are next considered. Then follow chapters upon industrial, military and camp, naval and prison hygiene. Exercise and training are well considered. Bathing and clothing next receive attention. The methods for disposal of the dead form an important chapter. Later the germ theory of disease is discussed, and chapters follow upon contagion and infection. A valuable article upon quarantine, from the pen of Walter Wyman, M.D., Surgeon U. S. Marine-Hospital Service, concludes the volume.

Preventive medicine, more than at any other period in the world's history, now commands the thought and study of the medical profession.

This work by Professor Rohé is a valuable contribution to the literature upon this subject, and as an American work it is all the more acceptable to those of us who have a special pride in the development of American literature. The volume will be found exceedingly instructive, and will commend itself to a large class of persons who are interested in sanitary science, but who are not members of the medical profession. To such, as well as to medical men, we commend the work.

A MANUAL OF THE PRACTICE OF MEDICINE. By FREDERICK TAYLOR, M.D., F.R.C.P. Physician to, and Lecturer on Medicine at Guy's Hospital; Physician to the Evelina Hospital for sick children; Examiner in Materia Medica and Pharmaceutical Chemistry at the University of London. With Illustrations. Philadelphia: P. Blakiston, Son & Co., 1012 Walnut St. 1890.

This valuable practical work of eight hundred pages from the pen of the well-known English author, Professor Taylor, is well worthy of a place in the libraries of American Practitioners. It deals concisely with the nature, course and treatment of diseases. Specific infectious diseases are very fully described, and his methods of treatment are judicious.

He considers the diseases of the nervous system in general, and specifically in a manner helpful to the practitioner; his descriptions being lucid and yet concise, and their treatments such as promise the best results. The diseases of the digestive organs, those of respiration, and of the circulatory system are carefully described, and the directions for treatment will be found especially suggestive to those whose means of library references are limited. The leading varieties of skin disease are well considered and their treatment indicated. His section on urinary diseases will repay a careful reading. By this reproduction of an English work upon Medical Practice the publishers have conferred a benefit upon the American medical profession. Price \$4.

A TREATISE ON MASSAGE. Theoretical and Practical; Its History, Mode of Application and Effects. Indications and Contra-Indications, with results of over fifteen hundred cases, by DOUGLAS GRAHAM, M.D. Second edition. Revised and enlarged. New York: J. H. Vail & Co.

In this revised edition of the author's work,—the first having appeared in 1874—is shown the same enthusiasm which characterized the first one. This serves a two-fold purpose. It inspires patients, for a time at least, with hopefulness, and stimulates the profession to further investigate its range and value as a therapeutic agent, both of which remain yet to be firmly established. Perhaps the author will have less occasion to complain of the want of familiarity of the medical profession with the subject of massage now than at the time his book first appeared.

Although the manipulations which now are known as massage were practiced, and with benefit, even prior to the Christian era, it is probable that at no time has the subject received more, if as much, attention than in the last decade. The comfort given by judicious practice of the art is not an inconsiderable matter in functional dis-

turbances. If it can be established that it will, in other cases, do one-half of what is claimed for it by its enthusiastic advocates, it should find a more prominent and a lasting place among our remedial measures.

In addition to the physical aspect of the subject, in its practical work, it has become apparent that there is also a moral one. It is not necessary to condemn a worthy measure because it may be perverted. It is, however, to be regretted that, as massage is now being tested on its merits, and from a scientific standpoint, any occasion should have arisen that so-called massage establishments, in our cities, should have made it necessary to place them under police surveillance, in the interest of public morality.

This book, in the eighteen chapters into which it is divided, covers the supposed range of the usefulness of the art, and is a fair exponent of what may be regarded as an enthusiast's conviction, based upon experience—his own and others—in a great variety of cases. The results are, at least, suggestive, and the book is not devoid of interest, although it may not, always, convince. It may be but a typographical error that fixes the period of the war of the rebellion in the United States as being "from 1860 to 1864."

MISCELLANY.

A HINT.—Last week Messrs. John S. Christian and Frederick Reistorf, druggists of this city, were each fined \$100 for practicing medicine without a license.

ERRATA.—IN THE JOURNAL of August 8, the article on the National Temperance Hospital was wrongly credited to Dr. J. Davis, instead of Dr. Chas. Gilbert Davis of Chicago.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.—This Association will hold its seventeenth annual session at the Pickwick Theatre, Washington and Jefferson aves., St. Louis, October 14, 15 and 16. A full programme of interesting papers has been prepared and provision has been made for the fullest, freest and most complete discussion of the same. Representative men from various sections of the country have been invited to open the discussions. The local profession of St. Louis is a unit to the end that every visiting physician shall be received and welcomed in a regular warm hearted, St. Louis style.

The same qualifications for membership in this Association are requisite as for the American Medical Association, the former being subordinate to the latter. If eligible, you and your friends, together with your wives and families, are most cordially invited to visit St. Louis and enter into the scientific work and the social pleasures as you may desire.

I. N. LOVE, Chairman Committee Arrangements.

AMERICAN GYNECOLOGICAL SOCIETY.—Programme of the Sixteenth Annual Meeting, to be held in the lecture room of the Columbian University, corner of 15th and H streets, Washington, D. C., on September 22, 23 and 24, 1891. Physicians are cordially invited to be present.

First Day—Tuesday, September 22.

Morning session at 9.30 o'clock. Roll-call, reception of guests, etc. Address of Welcome. By Dr. Joseph Taber Johnson, of Washington.

1. The Advantages of Mixed Anæsthesia in Gynecological Surgery. By Dr. John R. Reeve, of Dayton, Ohio.

2. Concealed Accidental Hæmorrhage During Labor. By Dr. Henry C. Coe, of New York.

3. Diffuse Adenoma of the Uterine Body. By Dr. James R. Chadwick, of Boston.

4. The Influence of Season on Recurrent Pelvic Inflammations. By Dr. Frank P. Foster, of New York.

5. The Therapeutic Aspect of Some Ovarian Disorders. By Dr. Edward W. Jenks, of Detroit.

Adjournment at 1 P.M. Afternoon Session at 2.30 o'clock.

6. Insanity Following Laparotomy. By Dr. J. M. Baldy, of Philadelphia.

7. Vaginal Hysterectomy by *Morcellement*; Technique and Indications for Operation. By Dr. Samuel Pozzi, of Paris, France.

8. A Clinical Study of Primary Carcinomatous and Sarcomatous Neoplasms between the Layers of the Broad Ligament, with Report of Cases. By Dr. Joseph E. Janvrii, of New York.

9. The Present and Improving Status of Cæsarian Surgery. By Dr. Robert P. Harris, of Philadelphia.

10. Unique Case of Multiple Neuro-lipomata following Laparotomy. By Dr. H. Marion Sims, of New York.

Second Day—Wednesday, September 23.

Morning Session at 9.30 o'clock.

11. President's Address.

12. The Treatment of Cancer of the Cervix Uteri by High Amputation; Second Series of Cases, with Additional Report on the First Series. By Dr. William H. Baker, of Boston.

13. The Advantages of Delivery in the Left Lateral Posture. By Dr. Henry J. Garrigues, of New York.

14. The Influence of Imperfect Development as a Cause of Uterine Disease. By Dr. W. Gill Wylie, of New York.

15. The Technique of Vaginal Fixation of the Stump in Abdominal Hysterectomy. By Dr. Henry T. Byford, of Chicago.

16. Can We Avoid Mural Abscesses and Ventral Herniæ after Laparotomy? By Dr. Horace T. Hanks, of New York.

Adjournment at 1 P.M. Afternoon Session at 2.30 o'clock.

17. Some Clinical Testimony as to the Ultimate Results of Removal of the Uterine Appendages. By Dr. Thaddeus A. Reamy, of Cincinnati.

18. Indications for Abdominal Section in the Treatment of Puerperal Pelvic Inflammations. By Dr. R. B. Maury, Memphis, Tenn.

19. A Study Relative to the Functions of the Reproductive Organs in American Indian Women. By Dr. Andrew F. Currier, of New York.

20. The Immediate Closure of Laceration of the Cervix. By Dr. Cornelius Kollock, of Cheraw, S. C.

21. The Conservative Treatment of Pelvic Tumors and Diseases. By Dr. Eugene Gehrung, of St. Louis.

22. The Anatomical Relations of the Lacerated Perineum to the Mechanics of its Causation. By Dr. Edward Reynolds, of Boston.

Business meeting, with closed doors, at 8 P.M.

Third Day, Thursday, September 24th.

Morning session at 9.30 o'clock.

23. In Memoriam.—Dr. Fordyce Barker, by Dr. James R. Chadwick, of Boston.

24. Ureteritis in the Female, by Dr. Matthew D. Mann, of Buffalo.

25. The Surgical Treatment of Retroversion and Prolapse of the Uterus, by Dr. Paul F. Mundé, of New York.

26. A Paper, by Dr. Theophilus Parvin, of Philadelphia.

27. Series of One Hundred Laparotomies; My Mistakes and Failures, by Dr. A. Palmer Dudley, of New York.

Adjournment at 1 P.M.

Afternoon session at 2.30 o'clock.

28. Laparotomy in Trendelenburg's Posture, with Exhibition of a New Operating-Table, by Dr. Clement Cleveland, of New York.

29. The Electrical Treatment of Uterine Fibroids in England, by Dr. George Keith, of Brooklyn.

30. Diabetes Mellitus Gravidarum, by Dr. Henry D. Fry, of Washington.

31. A Successful Porro Operation, by Dr. R. Stansbury Sutton, of Pittsburgh, Penn.

32. An Argument against the Stem pessary, or so-called Drain-tube, by Dr. Egbert H. Grandin, of New York.

There will be a lunch at the Arlington Hotel each day after the morning session, for the Fellows and invited guests.

Officers for 1891.—President, A. Reeves Jackson, Chicago. Vice-Presidents, Joseph Taber Johnson, Washington, William H. Baker, Boston. Secretary, Henry C. Coe, New York. Treasurer, Matthew D. Mann, Buffalo.

Other Members of the Council.—William M. Polk, New York; H. P. C. Wilson, Baltimore; Francis H. Davenport, Boston; E. C. Dudley, Chicago.

The Hotel Arlington will make a deduction to Fellows and Guests of the Society.

HYDRASTIS CANADENSIS FOR NIGHT-SWEATS.—Cruse has used the fluid extract of hydrastis canadensis with very good results in the night-sweats of phthisis. He gives it in doses of thirty minims, and often finds that the dose does not have to be repeated for some time.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from August 8, 1891, to August 14, 1891.

Asst. Surgeon John J. Cochran, U. S. A., died at St. Luke's Hospital, New York City, August 5, 1891.
Major Alfred C. Girard, Surgeon U. S. A., relieved from duty at Ft. Niagara, New York, and ordered to Ft. Sheridan, Ill., for duty.
Capt. John O. Skinner, Asst. Surgeon, assigned to duty at Ft. Clark, Texas.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending August 15, 1891.

P. A. Surgeon J. Baker, detached from U. S. S. "Palos," and authorized to delay reporting in the United States for six months.
P. A. Surgeon J. S. Sayre, detached from the U. S. S. "Ranger," and ordered to the U. S. S. "Palos."
P. A. Surgeon V. C. B. Means, ordered to the New York Naval Hospital, September 1.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Three Weeks Ending August 8, 1891.

Surgeon George Purviance, detailed as chairman, Board of Examiners. August 8, 1891.
Surgeon H. W. Sawtelle, to proceed to Portland, Me., for special duty. August 3, 1891.
Surgeon John Godfrey, to represent the Service at Seventh International Congress of Hygiene and Demography. July 25, 1891. Detailed as member Board of Examiners. August 8, 1891.
Surgeon Fairfax Irwin, detailed as recorder Board of Examiners. August 8, 1891.
Surgeon F. W. Mead, granted leave of absence for thirty days. July 30, 1891.
P. A. Surgeon H. R. Carter, granted leave of absence for thirty days. August 8, 1891.
P. A. Surgeon D. Carmichael, granted leave of absence for thirty days. August 3, 1891.
P. A. Surgeon W. J. Pettus, to proceed to Wilmington, N. C., for temporary duty. July 31, 1891.
Asst. Surgeon J. C. Perry, granted leave of absence for twenty-seven days. July 28, 1891.

ORIGINAL ARTICLES.

SIMPLE METHODS OF SEWAGE DISPOSAL.

Read in the Section of State Medicine, at the Forty-second Annual Meeting of the American Medical Association, Washington, D. C., May 5, 1891.

BY C. W. CHANCELLOR, M.D.,

SECRETARY STATE BOARD OF HEALTH, BALTIMORE, MD.

Among the many problems engaging the attention of sanitary engineers, that which embraces the removal or disposal of household sewage, is perhaps the most important. With the advance of natural sciences, the principles which are recognized as governing health and disease have been gradually developed, until we are now face to face with the fact that if we would be free from filth diseases, it is necessary to remove from our midst those elements which are either their direct cause or agents of transmission.

The question resolves itself into disposing of such matters in a manner best suited to the conditions and locality in which they are produced, having regard:

1. To the sanitary efficiency of the method employed.
2. To the economical attainment of the result aimed at; and
3. To the method of disposal affording some return for the means expended.

The conclusions which naturally follow the foregoing propositions, and which, from a sanitary standpoint, dominate the whole question, may be summed up as follows:

- a. That wherever there is excretal refuse to be disposed of, it should be so treated as to remove or separate the solid from the liquid parts.
- b. That the impurities conveyed by the liquid parts of sewage, which are more readily oxidized, are insignificant as compared with those of the solid parts.
- c. That the solid parts of excretal sewage should never under any circumstances be allowed to enter a water-way; and if the fluid parts can be subjected to some artificial process of purification, and subsequently passed through the soil by subsurface irrigation, so much the better.

These are fundamental axioms which require

no discussion; but it must be admitted that, thus far, serious difficulties have environed the practical application of these principles to the question of sewage disposal.

Apart from the question of health, the practice of discharging crude sewage into water-courses has its attendant evils. The solid matters will gravitate to the banks and bed of the stream, which not only obstructs natural drainage, but is liable to decompose and become offensive as the water falls, and exposes it to the action of the sun and air. Again, the more finely diffused solid particles are exceedingly hurtful to fish, choking up their gills and suffocating them. Moreover, fish breathe by means of the free oxygen which is contained in the water in which they natate, and this element being deprived of its oxygen by the admixture with sewage, the fish must necessarily die.

This fact alone, viewed in the light of political economy, should restrict the amount of sewage poured into any limited area of water; for however admissible *fresh* sewage may be as food for fish, it soon becomes stale, and in this condition acts as a poison which will eventually destroy the fish and oysters of any water area into which it is discharged.

Again, when sewage passes into a putrefactive state, the gases that are generated either in sewer pipes or water-courses, are capable of producing certain malignant diseases; but whether the illness is to be regarded as the direct effect of inhaling the mixed chemical gases, or as an expression of the consequences of inspiring a micro-organism which is reproduced in the human body, is not known to medical men—who are, however, perfectly familiar with the illness.

One of the greatest difficulties of adequately dealing with this sewage question, lies in the enormous bulk to be operated upon—equal to about 5 gallons of water to every 3 ozs. of fecal matter—and it is therefore reasonable to suppose that, could some simple mechanical appliance be devised by which the liquid could be drawn off and separated from the solid parts, it would greatly assist in the efficient treatment of excretal refuse. The fluid part need not necessarily be passed directly into a water-course; it could be first distributed by subsurface irrigation over a sufficient

area of land, for which it would serve as a useful manure, and by which it would be effectively filtered and still further purified. The employment of such a method is the more to be recommended because, when a process of separation only has been employed, as contradistinct from a process of precipitation with chemicals, the effluent is richer in organic substances available for the nutrition of plant life, and the solid matters being excluded, the pores of the soil will not become clogged.

As to the manurial value of the solid matters retained, that must be judged rather by the practical results of the agriculturist than by the presumed theoretical values based on analytical data. The percentage of combined nitrogen, however, in this material is remarkably constant, and the phosphoric acid which it contains is also an important ingredient in an agricultural point of view.

Fæcal matter has been termed "the natural food of the soil," as it returns to the soil those elements which are taken from it by the growth of vegetable products necessary for the proper nutrition of man. By treating excrementitious matters by a process of separation, moreover, what is now a nuisance to cities and towns may be made a source of profit to the country generally, especially to the agriculturist, who would find in the solid matters a valuable guano—superior to most manures in the market—produced at his own door.

"The most fertilizing and effective manure," says Victor Hugo, "is human manure; but what is done with this golden dung? It is swept into the gulf! We send, at great expense, fleets of ships to collect at the Southern Pole the guano of petrels and penguins, and cast into the sea the incalculable element of wealth which we have under our own hands."¹

If this so-called "golden dung" has the value that is ordinarily attached to it, private enterprise would surely be rewarded for its collection and utilization, and could well afford to pay a handsome bonus for its preservation. Agriculture, so important a factor in the country's industry and prosperity, has up to this time suffered such heavy losses from this material being "cast into the gulf," that, apart from the question of health, its interests are fully entitled to the serious consideration of political economists and legislative bodies.

It has been asserted that one prime cause of the fall of the Roman Empire was the building of the great sewers of Rome, and the consequent disastrous deflection of what might have been an enormous fertilizing material, into the Tiber, where it went to waste.

The Chinese are said to preserve carefully everything that can be used to enrich the earth for food production, and there seems to be a growing dis-

position, both in Europe and America, to follow their example, by devising measures and making experiments to utilize excretal refuse for enriching the soil; but we must admit that there is still a squandering of this valuable material that may well alarm the political scientist.

It is, undeniably, of the last importance that household sewage, which is now allowed to go to waste with a reckless disregard of both public health and agricultural prosperity, should be utilized in some cheap, cleanly and simple fashion; and surely, the ingenuity of man can be applied in no more useful way than to a proper solution of this important question, which embraces not only the welfare of society, but even the integrity of nations.

Passing by the difficulties which are unmistakably attendant upon the disposal of sewage in large quantities, the question comes up, how is it to be treated, as treated it must be, if the health of the inhabitants of our towns is to be considered? The methods of treatment, other than those involved in the systems by which the whole of the sewage is sent into water-courses—if, indeed, this may be considered a system of treatment at all—and in applying crude sewage for the irrigation of land, are pretty numerous; but numerous as they are, they all come under one or the other of the following classes:

1. Dealing with excretal refuse in a special way, altogether separate from large sewage drains, leaving these to conduct the waste waters of domestic and industrial operations and also the rain or storm waters alone.

2. The precipitating process, by which the solid organic and putrescible portions of the sewage are deposited in a solid form, which may be used as an ordinary manure, passing the liquid portion, in a condition more or less clear, into some stream or river.

3. Keeping the rain or storm water on the surface, or sending it into drains distinct from those conveying sewage, to be discharged into some river or stream; while the crude sewage, in a more concentrated form, is also passed into the water-course, or on the land for irrigation purposes.

4. A combination process of straining, precipitating and filtering, by which the solid part of the excreta is separated from the liquid, as it were, at the fountain head, and retained in a hermetically closed vessel or tank, under a column of water, while the fluid parts, with the ordinary water of the closet, are passed through the meshes of a fine strainer, and then either run into the soil by subsurface irrigation, or filtered through some oxidizing agent, as burnt or spongy iron, to be subsequently discharged on the surface of the ground, or into a water-course.

Under the first of these four classes there are a number of arrangements which, when taken col-

¹ *Les Misérables*, p. 290.

lectively, may be termed the dry system of collection.

The cess-pit and the midden were the first attempts at collecting excreta, not so much, however, for the purpose of profit as with the idea of preventing nuisance. The cess-pit need only be mentioned to be condemned. The ash pit midden, or privy, has its advantages and its difficulties; of the difficulties, the education of the people to use them properly is chief—a difficulty, however, that applies quite as much to water-closets as to middens.

FIGURE 1.

The general principle of the ash pit midden or privy system is illustrated in Figure 1. It consists of a common privy, with a small covered ash pit, from the top of which, a ventilating shaft is taken to the roof of the house to which it is attached. The floor of the ash pit is of glazed earthenware, absolutely water-tight. The ashes used as an absorbent are emptied into the pit through the privy seat, whenever the closet is used. These pits are cleaned as often as may be necessary. This system is used at Hull, England.

The Manchester method, Figure 2, consists of a common privy, outside the house, constructed with a sunken pit, in which stands a galvanized iron receptacle, placed under the seat of the closet.

The floor of the pit is of earthenware, and the ventilation is through the flue as shown in the illustration. The door for removing the receptacle is at the side or back. In the absence of the receptacle, the ash pit can be used. The receptacle is emptied weekly.

The Rochdale method is similar to the Manchester, except that the wooden pail, generally

made from a kerosene barrel, is substituted for iron, and sits immediately beneath the closet seat and on the same level of the floor, instead of below the surface of the ground, which makes removal more difficult. Figure 3 is an illustration of the Rochdale system.

The Goux system consists in lining the inside of the tub with absorbents as charred sea weed or dry earth, rammed in by a central core, so as to give a uniform lining to the tub, thus preventing splashing. This method necessitates the frequent removal of the excreta. The faecal matter is received in the central cavity of the lining.

FIGURE 2.

At Birmingham, where the galvanized pails are used to the extent of some 40,000, representing a population of 250,000, the contents are collected weekly. These are emptied into a vat at the place of deposit, and some sulphuric acid added to fix the ammonia.

The object of these several methods is the conversion of the old and dangerous system of privy pits into receptacles calculated to promote health and decency, and keep out from sewers as much of the excremental matter as possible. There is no doubt whatever of the fact that either of these systems is infinitely more healthy and more reasonable in every way than the cesspool, and, personally, I am strongly inclined to think that a dry system of collection in villages and small towns, even if not in larger centres of population, is to be recommended in preference to the usual water-carriage system.

Lastly, we have among the dry systems of collection, Moule's dry earth closet, in which the deodorizing and absorbent power of the earth is applied to the treatment of excreta. This closet is illustrated in Figure 4.

However efficient as a deodorizer and absorbent dry earth may be, there are almost insuperable difficulties attendant upon its use, which have retarded its general introduction, even in country districts. About four and one-half pounds of dry earth per head per day are required to obtain a consolidated and inoffensive compost. A village of 1,000 persons would need, therefore, about two tons of dry earth per day. Moreover, it is a *sine qua non* that no liquids are to be discharged into the closet, so that it is a system which does not provide for liquid excreta; or if the air is very damp, which is the normal condition in certain places, or if the contents get moist in any way, we have, to all intents and purposes, a cesspool without its advantages, or without the special precautions that are commonly taken with regard to cesspools.

purpose of precipitating from the water certain matters which are therein suspended.

The third plan is that by which the great dilution of sewage with water is proposed to be avoided by having two distinct sets of drains, one to convey away the household sewage alone to some water-course, or to be treated by precipitation or subsurface irrigation; the other set of drains to carry off storm and street water. This was first proposed half a century ago by Mr. F. O. Ward, of England, and was subsequently practically carried out by Mr. Menzes, at Eaton, and, more recently, by Col. Geo. E. Waring, at Memphis. There can be no doubt that if the rainfall could be excluded from the sewage proper, a vast step would be gained towards the practicability of usefully applying sewage to the soil, but even then the area of land required

FIGURE 3.—ROCHDALE PAIL CLOSET.

A, excrement pail. B, ash tub. C, seat cover (raised). D, iron collar below seat, reaching slightly into pail when cover is down. E, hinged upright of seat. G, door admitting from outside to excrement pail.

We come now to consider the precipitating processes. A great number of these have been tried, but the general result seems not to have been satisfactory, since none have thus far been free from a feature which practically condemns the whole of them, viz., the employment of expensive chemicals in large quantities for the

would be so great and the cost of preparation so immense that the suggestion has been considered by high authorities to be hardly practicable. Moreover, it has been pretty well established that the putrefactive decomposition of solid excretal matter in soils gives rise to the production of malarial and parasitic diseases, and that such

solid organic matters, after a time, will form a crust or cake upon and in the interstices of the soil, which gives off offensive and dangerous effluvia. Again, the sub-soil water from broad irrigation is charged with decomposing matters, and Petenkofer is not alone in his opinion that "there is no more fruitful source of disease than polluted sub-soil water which is constantly changing its level."

FIGURE 4.—DRY EARTH CLOSET.

The mere fact that the available land near large cities, at least, is insufficient for the disposal of sewage by irrigation, is sufficiently condemnatory of the process as an exclusive means of utilizing sewage. According to M. Lefeldt, an acre of land is required for the excreta of every twenty or thirty persons when applied by broad irrigation; while Mr. Henry Robertson, of England, in a paper on sewage disposal (*Sanitary Record*, 1884), contributed to the Sanitary Institute meeting at Dublin (1884), states that "open porous land with a good free sub-soil drained six feet deep, will deal, per acre, with the sewage of 600 people," but the cost of preparing the land he estimates at from \$4,000 to \$5,000 per acre, so that, practically, it does not much matter which kind of irrigation be used.

The theory of purification by irrigation is that the fluid part of sewage gradually percolates through the land, and is finally carried off by the artificial under drains, while its organic con-

stituents are subjected to oxidation by the agency of microorganisms producing the phenomenon known as "nitrification." The solid parts left in the soil are also attached, and gradually succumb to the influence of hydration and oxidation; but there is a limit to this process, and should the land become overcharged or choked with solid matters, which often occurs on sewage farms, oxidation will not proceed, and an intolerable nuisance ensues.

To prevent this the separation of the solids from the fluids of sewage is essential, and after this the effluent may be disposed of with entire immunity by a process of irrigation; or, in the absence of special objections, the effluent may be discharged into a river or other water area having sufficient volume or flow to oxidize the organic matters which are held in solution. This, however, applies only to sewage, whether mixed with rain water or not, that has been so dealt with by screening, subsidence, precipitation or otherwise, that the solid parts are removed from the liquid parts.

If our boasted scientific knowledge is worth anything, it should enable us to separate the fluid from the solid parts of excretal sewage, and to convert the latter into a good practical manure, while the fluids may be discharged into the soil, or into some water-course, in an innocuous condition.

Some three or four years ago Mr. C. T. Kingzett, the distinguished London chemist, suggested that a small portable apparatus might be supplied to each house, provided with a strainer, whereby the water of crude sewage would be separated from the solid parts; and the receivers could, by a properly organized system, be collected as often as necessary, and a clean one left in the place of the one removed. Such an apparatus, it scarce need be said, should be as simple and as economical as possible, consistently with preventing nuisance or danger to public health; and I claim for a device which I have lately introduced, that it is at once the most simple, the most effective and the most economical that has yet been proposed for the purpose. The method consists of a process and apparatus by which the solid matters of household refuse are effectively separated from the water of crude sewage by mechanical straining, subsidence and precipitation, whereby a large proportion of the suspended matters are detained in a hermetically closed receptacle, which when full can be removed and replaced with an empty one by a common laborer, while the liquid parts are continuously delivered in such a condition of purity, that they may be used to irrigate the soil with advantage, and without any danger of choking its pores; or the effluent from the precipitating tank may be further purified by filtration through iron to such an extent that it can

be discharged into any drain, sewer, cesspit, river or stream with entire immunity. The apparatus is illustrated in the following diagram :

Figure 5 represents a vertical section of the apparatus with all its parts intact, except the filter, which is omitted as it is rarely to be used. *A*, represents the receiving vessel or "receiver;" *B*, the settling or "precipitating tank;" *D*, the outer cylinder of the "strainers;" *E*, the inner perforated "strainer;" *F F*, the soil pipe connected with the strainer *E* above and below; *G*, the collar which connects the soil pipe with the receiver; *H*, the box or holder for the precipitating reagent; *I*, pipe connecting the receiver and precipitating tank for the purpose of drawing down the water to prevent slopping when the receiver *A* is detached at the cellar *G* to be removed. When detached the opening at *G* is closed with a close-fitting cap.

has allowed to pass, sink by gravity to the bottom of the receptacle, while the matters that are more or less dissolved in water find their way along with the supernatant liquid of the sewage through the meshes of the strainer, and from thence by a connecting pipe *D* into the precipitating tank.

The precipitating tank receives the overflow from the "receptacle" which has passed through the strainer. This tank is provided with an automatic device for discharging a certain quantity of chemical precipitants into its contents. The supernatant liquid in the precipitating tank, already quite pure, is discharged through the pipe *h*, which, when the effluent is to be disposed of by sub-surface irrigation, is converted into a siphon simply by extending this pipe downward, on the inside of the tank, to a point near the bottom. In this way the flush through

FIGURE 5.

The operation of the apparatus is as follows : All such matters as are generally discharged into the soil pipes of houses are conveyed into the "receptacle," which is removably connected with the soil or drain pipe. The coarser, undissolved matters, such as foreign bodies, ordure, and paper not yet dissolved, which the trap of the soil pipe

the sub-surface irrigation pipes becomes rapid and continuous until the tank is emptied.

The receivers, containing the solid parts of excretal matters, are to be collected, when full, by a properly organized system, and clean ones left in their places. These receivers should be taken directly to the usine or compost factory,

where their contents may be worked up, with other substances, it may be, into an innocuous and valuable manure powder ready for immediate application to the soil. The utilization of the solid excreta is not, however (and this is a very important matter to public bodies which have to do with the disposal of sewage), confined in any sense to its employment as a manure, or as a source of ammonia and certain salts. It may be pressed, air-dried, and employed as ordinary fuel for use in boilers or other furnaces. Further, it may be ground up with clay and lime, and converted into brick or cement after the process devised by the late General Scott, of England; or, again, it may be admixed with other materials, such as are ordinarily employed, and converted into a material for use in the construction of sidewalks, foundations of buildings, etc.

INCIPIENT CATARACT; ITS ETIOLOGY, TREATMENT AND PROGNOSIS.

Read in the Section on Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY S. D. RISLEY, A.M., M.D.,

ATTENDING SURGEON AT THE WILLS EYE HOSPITAL, PHILADELPHIA; LECTURER ON OPHTHALMOLOGY IN THE UNIVERSITY OF PENNSYLVANIA; PROFESSOR OF OPHTHALMOLOGY IN THE PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE.

In a brief paper published in the *University Medical Magazine* for March, 1889, I called attention to the underlying pathological factor in the etiology of *hard cataract*, and entered an urgent plea for the treatment of eyes afflicted with advancing opacity of the lens, before the stage of maturity. It was then claimed that by designating these cataracts as "*senile*" the tendency had been introduced to regard them as one of the unavoidable changes incident to the decline of life, and that by this means attention had been drawn away from other and more important factors in their production. It was shown that the hard and inelastic lens of even advanced life was not necessarily an opaque lens, and that approximately normal acuity of vision was quite compatible with old age. That the opaque lens was therefore an extraordinary occurrence to be explained by other causes than senility.

In my early experience, when consulted for relief from commencing cataract, the habit was to acquaint the patient or his friends with the cause of the failing vision. The opinion expressed was to the effect, that for the present nothing could be done to restore the vision—on the contrary, it would probably grow steadily worse, but that though blindness might and probably would insue in one or both eyes, vision would then be restored by removal of the "*ripe*" cataract. The conjunctival irritation quite habit-

ually present was relieved by mild astringents, advice given regarding the general course of life in its relation to the laws of hygiene, and the patient requested to return occasionally for inspection. Thus the individual and the family were sent away with an abiding solicitude hanging like a cloud over the household, the anxiety—alleviated only by the hope when the worst had fallen—relief would come in the extraction of the mature lens. A more careful study and a steadily widening experience, have convinced me that in a considerable group of these afflicted persons a more hopeful prognosis can be given. In many of them the progressing opacity can be arrested; in still others the rapid increase can be greatly retarded, and failing in this the eye will be in a more favorable condition for operative interference, by virtue of the treatment instituted. For many years, I have with increasing confidence given this opinion to persons applying for relief from their failing sight, consequent upon the blurring lens fibres and the associated conditions, which it is here claimed sustain to each other an etiological relation, and are in large measure amenable to treatment. In the present paper no new facts are brought forward, but at the request of the chairman of the Section it gives me pleasure to once more call attention to the views before expressed, which I do with increased confidence after two years of additional experience, and a more careful study of the data at my command. The clinical picture I have in mind does not include those cases of stationary opacity in the peripheral cortex of the lens, occurring in otherwise normal eyes. Every surgeon must have had frequent opportunity to study these cloud-like bands hanging between the lenticular pole and periphery, usually situated in one of the lower quadrants, or a dense bank of opacity, well down in the periphery, remaining year after year unchanged, and causing the individual no inconvenience. That no misunderstanding may occur as to the claims to be made for the treatment of beginning cataract, I wish to say that I have never seen an established opacity of the lens disappear. In my experience, an opaque spicule once formed has remained or increased. When, under treatment, vision has improved, it has not been from the removal of the opacity in the lens fibres, but from the improved condition of the vitreous body, the retina and choroid. Nor is it intended to include in this study directly, the considerable group of cataracts, which, by common consent, are regarded as "*complicated*" or secondary, *e. g.*, the opacity of the lens which is a part of the closing scene in eyes lost from retinal detachment, inflammatory glaucoma, and irrido-choroiditis. No form of eye disease is more familiar to the surgeon than the posterior-capsular opacities *et al.*, which accompany and are dependant upon the more

pronounced forms of intra-ocular disease involving the choroido-retinal tract. While these violent forms of disease are not included in this discussion, they are alluded to as pointing in the most unmistakable manner to the important possible relation existing between disease involving the nourishing membranes of the eyeball and the impaired nutrition of the vascular lens. It is probable that we might, with the greatest propriety, regard these complicated cataracts, so-called, as illustrations of a more advanced or violent type of disease, than that here contemplated. There is, however, a very large group of eyes suffering from irritation and chronic inflammatory processes of the retino-choroidal tract which do not present the gross ophthalmoscopic changes which characterize the destructive diseases above referred to, but which may, and doubtless do lead up to them under provocation. Eyes which by virtue of their chronic or subacute pathological state are ripe for more destructive processes, which are lighted up by the onset of some constitutional disturbances, or by some extraordinary exertion or exposure to light or heat. They may or may not be associated with some systemic dyscrasia. Frequently, commencing early in life, they are steadily progressive unless arrested by appropriate treatment, and sooner or later undermine the health of the eyeball, rendering it throughout life especially liable to various forms of acute disease, and are the more or less direct cause of the serious maladies to which the eyes are subjected during and after the middle period of life. To this category belong especially the eyes starting in life with errors of refraction.

The clinical picture presented by this group of *weak eyes* is important to our purpose. Subjectively, we have the familiar picture of asthenopia. They present, however, a characteristic group of objective phenomena which I design to connect with the forms of disease so frequently seen after forty-five years of age, and especially with opacification of the lens. Much has been written to establish the relation of cause and effect between eye strain and the inflammations involving the choroid and retina and the external tunica. A bibliography of this field of observation is no longer necessary, since it has been well established in the practice of ophthalmic surgeons. The woolly choroid or fluffy eye ground, with the two capillary nerve surfaces; the ragged nerve margins; the ripe-peach choroid; the narrow crescent of choroiditis embracing the temporal margin of the optic nerves, and its steady advance to the large atrophic conus or posterior staphyloma of the distended myopic ball, are well understood, but I am not so sure that we habitually connect with these intra-ocular disturbances the affections of the external tunica. The chronic hyperemia of the conjunctiva, and

dilated anterior perforating vessels, the swollen and red coruncles, the blepharitis ciliaris, the increased secretion and partial retention of tears, the recurring styes, are frequently but the external expression of the grave disturbances of the circulation of the intra-ocular tunica.

It were cause for surprise if, in the presence of this general disturbance of the nourishing membranes of the eyeball, the vitreous body and crystalline lens, divorced as they are from a direct vascular supply of nourishment, did not frequently suffer in their nutrition. Indeed, reasoning *a priori*, one would anticipate a proneness upon the part of these avascular structures to accept disaster, in the presence of any cause which would impede their ready supply of nutriment.

I have elsewhere urged that the chronic hyperemia of the very vascular choroid, however produced, by increasing the contents of the globe, brought about increased intra-ocular tension. That in the readily yielding sclerotic of youth is presented to us the interesting clinical phenomena of increasing refraction, and finally progressive myopia. Later in life, however, the changed anatomical conditions materially alter the clinical picture. Here, in the presence of the rigid sclera, we find the conditions which give rise to the cases of violent asthenopia, from intra-ocular pressure, which too frequently passes over into the better appreciated and easily recognized phenomena of glaucoma.

The mechanical interference with the circulation is important. It is obvious that increased intra-ocular tension, however slight, must produce the mechanical result of interference with the circulation of blood and secreted fluids through the organ. The veins being more readily compressible than the arteries, would not as readily, under pressure, empty the eye of its venous blood, which, as a physical necessity, would control in a measure the ingress of the nourishing arterial supply. By this mechanical means, the circulation would be at least measurably retarded, and the nutrition of the organ suffer a proportionate interference. In like manner the lymph channels and absorbents would be in a measure defeated in the proper performance of their functions. It is simply reasonable to suppose that these avascular tissues, the vitreous body, the lens and cornea would be prone to suffer harm, and the correctness of such reasoning is borne out by clinical experience, since in it we find a sufficient explanation of the steamy cornea of inflammatory glaucoma, the hazy vitreous with its web-like opacities in irido-choroiditis or cystitis, and the swollen, opalescent lens, with peripheral spiculæ of opacity, and the steamy nucleus of incipient cataract. In youth these phenomena are averted by the relief of pressure through the expansion of the globe,

but nevertheless result in the evils of progressive myopia.

While the uncorrected errors of refraction, particularly in the educated classes, and in those whose vocation demands accurate vision at a near point, are doubtless the most frequent cause of the choroidal conditions which are here described, there are numerous other causes, which are sufficient in themselves to set up and maintain an analogous choroidal state, and are equally baneful in producing the dangerous sequelæ which befall the eye after forty years of age. Among the most important of these causes is exposure to light and heat: *e. g.*, in the case of the artisan at his work-bench, facing, with his unprotected eyes, a window or gas-jet for many hours in every day; the cook over the heated range; glass-blowers, puddlers, stokers and engineers. Such persons are quite uniformly the subjects of subacute choroiditis, presenting pigment clouds and absorption splotches in the choroid, and red optic disks, with blurred margins, and very often with fine webs in the vitreous, or impaired transparency. It has fallen to my lot to see many examples of this, and, in not a few, posterior capsular opacities and opaque spiculæ in the margins of the lens. At my request, Dr. George E. de Schweinitz examined twenty-five men employed in one of the most extensive iron works in this country, selecting those whose employment exposed them to the intense light and heat of the molten metal. With only two exceptions, these men were subjects of well-marked choroidal disturbance. It was interesting to note that the most marked changes were present in that eye on the side which the man habitually turned toward the furnace in working the heated metal. Other causes were carefully excluded in every case.

Another fruitful source of trouble is the prevailing notion that it is best for the patient to avoid the use of presbyopic glasses as long as possible. It is obvious that all the evils attending upon eye-strain are here present even in the emmetropic eye, and that, too, at a period of life when the attending dangers are enhanced.

I recall the case of an eminent clergyman, æt. 50, with emmetropic eyes, who, although an industrious student and author, had not worn glasses. He came complaining of burning eyes, with a sense of fullness or tension, during and after his work, and severe occipital pain, which caused him not a little anxiety, because of its possible grave import. He had marked choroido-retinal irritation, and suffered greatly from insomnia. He received presbyopic glasses, and in a few weeks his headache and insomnia had disappeared, and with it his anxiety about his anticipated nervous break-down.

A still more marked example of the possible results from this erroneous habit of avoiding the

use of glasses to correct presbyopia was presented in the following case:

A postmaster, in robust health, æt. 49, with a low grade of H. As, had managed to attend to his duties without the aid of glasses. He complained of muscæ, blind spells, diplopia on looking up after reading—which occasionally persisted to his great annoyance—and insomnia. He had pin-head pupils, shallow anterior chambers, red and watery eyes, increased tension, and dilated anterior ciliary vessels. His vision, however, was nearly normal, but failed quickly. There was no contraction of the field. The symptoms slowly disappeared under correcting glasses, but not until after prolonged use of homatropia and rest. Here, too, there was well-marked eye-ground changes. Glaucoma in this case seemed to be imminent.

In looking over the clinical records I have been struck with the much greater frequency with which the lower part of the lens was involved than the upper, the commencing opacity almost habitually being below. It is in the lower part of the choroid also we ordinarily find the most marked pathological change, in many cases, particularly in clerks who sit facing window or gas light at their work, or in the case of artisans who are frequently compelled to stand at the work bench facing the light.

There is probably no question in the minds of ophthalmic surgeons regarding the causes of the choroidal engorgement and disease, but it is my purpose to show, that there is a positive relation between this choroidal state and the lenticular disease. That these deductions are not based upon purely theoretical grounds find ample demonstrations in the following statistics gleaned from my private case-book by Dr. John T. Carpenter, Jr.

A brief analysis of eighty cases with incipient cataract gave the following interesting results. The ages ranged from one æt. 26 years to one æt. 87 years, and presented all stages of development of the opacity.

In *thirty-seven* cases there was a clear history of "weak eyes" and long standing asthenopia, *i. e.* headache following use of the eyes; recurring styes, ophthalmia, etc., often dating back to childhood. In the remaining cases there was either no note bearing upon this point, or it was noted as absent. There was demonstrable refraction errors present in *fifty-eight* cases—either in one or both eyes. These errors were also noted as present if, *e. g.*, the individual brought his glasses, worn for distance before the failing vision from his cataractous lenses was observed, even though the opacity was too far advanced to permit the determination of the refraction at the time of the consultation.

In the remaining cases it was either impossible to determine the state of the refraction, or its

study had been neglected since. No information could be gained from the records. Vitreous opacities, webs, etc., are noted as observed in *twenty-two* of the cases, and chroiditis in *fifty-eight*. In many of these areas of pigment absorption, macular disease, choroidal splotches and other gross changes are carefully described, as present in one or both eyes. The wooly choroid, crescents of chroiditis at margins of the nerve and pigment absorption, "ripe peach" choroid etc., are included in this group, if the conditions were sufficiently marked to be justly regarded as a disturbing factor in the nutrition of the eye.

In some instances the opacity was too far advanced to admit of any study of the fundus oculi, on one side, but if choroidal changes or vitreous opacities were present in the better eye, the case was included as one of choroidal disease, whether the eye in which the study was made presented lenticular opacity or not.

The frequency with which the affections of the external tunica was noted as present forms also a striking feature of this group of cases. The conjunctival irritation, partial retention of tears, swollen caruncles, and blenorrhœa of the lachrymal sac were observed in *forty-five* cases. In the remainder the record was silent. The frequency with which affections of the lachrymal sac had been noted and treated, was a source of surprise.

The number of cases might have been greatly enlarged, but these were sufficient to show the very obvious relation which exists between the formation of opacities in the crystalline lens, and local pathological conditions, and if they serve to show that incipient cataracts, in many instances, belong in the category of possible preventable diseases of the eye, the purpose of the essay will have been attained.

Among the many interesting details which appear in the study of these cases, is the fact that after the opacity has advanced sufficiently to prevent the use of the eyes at near work, and to exclude the light, that then the asthenopia and external inflammation gradually subsided. It is probable that the enforced rest thus secured to the eye permits also the gradual subsidence of the choroidal disease.

In this fact Nature affords us a suggestion for the management of these cases at an earlier stage in their history, when by rest and appropriate treatment, it is still possible to cure the choroidal disease. If the progress of the opacity is not by this means arrested at a point where useful vision is still possible, the prognosis upon operative interference would be more favorable than would be the case in a badly nourished organ.

The following cases related in some detail have been chosen as typical of the conditions described, and as incidentally illustrating the practical advantages which must follow advice based upon the views here set forth.

Case 1.—Incipient Cataract, Choroiditis, Asthenopia, Failing Vision. Mrs. L. æt. 63, consulted me in May, 1879, complaining of weak eyes, failing vision, headaches, to which she had always been subject, itching and burning of the eyelids. Recently she had made repeated changes in her reading glasses but without material benefit—three times within the year.

The caruncles were swollen and the conjunctiva was injected. V $\frac{2}{8}$ in each eye. She wears +.50 D. for near work, and with it reads Jr. 4. with difficulty.

The ophthalmoscope reveals a hazy image of the details of the fundus. The anterior chamber was shallow, pupils reacted to light and shade, and dilated to large medium under a mydriatic. The lens was now seen to be opalescent throughout, and at the inner border there was a cloud-like opacity and a few spicules of opaque lens projecting along the posterior capsule toward the pole.

In the left eye there were also numerous opaque spiculæ along the border of the lens, and a cloud in the outer part. There were in both eyes vitreous webs, which, with a convex glass, could be seen to move with a slight to and-fro movement with the motions of the eyes. The use of the eyes for all near work was forbidden, and a tonic and alterative treatment advised.

A weak solution of atropia with an astringent wash were directed locally. A month later V. had risen to $\frac{2}{4}$ in each eye, and the general discomfort and headaches much diminished. She then received +9, for reading, and was allowed to do a moderate amount of work. In 1883, she was last seen. The vitreous webs still remained, but the swelling and opacity of the lens had not increased, a much clearer view of the eye-ground could be had, and her general condition had much improved.

At her first visit she had been advised of the threatened cataract, and that in all probability her vision would grow worse. The gratifying result of treatment was a surprise both to the patient and myself. Without such treatment there can be but little doubt that the lenticular opacity would have advanced to ripe cataract.

Case 2.—Hypermetropic Astigmatism, Asthenopia from childhood, Failing Vision, Choroiditis, Incipient Cataract. Progress arrested. Mrs. T., æt. 60, came in January, 1884, because of recent rapid failure of vision, both for near and distant objects, and that she could not get glasses to aid her.

O. D. V= $\frac{2}{8}$ O. S. V= $\frac{2}{7}$. Not improved by any glass. No note was made of the external condition of the eyes.

She had been a great sufferer from headache all her life; had even as a school girl recognized the relation between the use of her eyes and the onset of pain in her head. Both lenses were strong-

ly reflecting. After dilating the pupils both lenses were opalescent, nuclei plainly outlined, and sectors of lenses visible, and there were innumerable small spiculæ in the periphery. With the strong illumination of the inverted image, the blurred details of the fundus could be seen, revealing well-marked choroiditis. She was on her way to her home in Kentucky, and could not stay for treatment. She was apprised of the nature of her trouble, and the importance of rest for the eyes was insisted upon. Potassium iodide prescribed internally, and a weak solution of sulphate of eserine locally. She returned a year later, January, 1885, having at first experienced relief from her headache, but lately it had returned, and with it increased fogginess of her vision. Potassium iodide and bromide were now prescribed, and homatropine locally, together with protecting smoked glasses. Numerous unsuccessful attempts were made to improve the vision by glasses. After a month, during which the treatment had been faithfully carried out, she selected without difficulty, although the opalescent condition of the lens remained as before, O. D. + .50 s. C — 2c. ax. $150^\circ V = \frac{2}{3}$. O. S. — .75 c. ax. $90^\circ V = \frac{2}{3}$. These glasses were prescribed for distance, and another calculated from them given for reading. The internal use of potassium iodide, alternating with iodide of iron, was continued for another month, when she was allowed to return to her home. Two years later she sent report by a relative that there had been no return of trouble, and that she was using her eyes without anxiety or pain.

In this case the usual train of symptoms and local appearances were presented which characterize the incipient stage of cataract, viz.: the failing or "foggy" vision, the swollen opalescent lens and peripheral spiculæ. Under treatment, which improved the health of the choroid, the vision improved, notwithstanding the fact that no change had taken place in the opacity of the lens fibres. The mixed astigmatism in the right eye, and the simple myopic astigmatism in the left, were doubtless important factors in the life-long history of these eyes.

Case 3. Choroiditis, Simple M. As., Vitreous Opacities, Incipient Cataract.—Mrs. H., æt. 63, November 10, 1884, complains of recent rapid failure of vision, which has progressed until she can no longer get a glass with which she can read. Has been near-sighted since about 15 years of age. Is certain that in early childhood she was not myopic. Any attempt to look at near objects brings on smarting sensation in the lids, and lachrymation. Eyes are red and watery, and have been so for many years. Strong white reflex from the small pupils on both sides, and anterior chamber in both eyes shallow. After dilatation both lenses were found to be opalescent, steeple-like projections from all parts of their

periphery, the centres still remaining sufficiently clear to permit a foggy view of the eye-ground. There were numerous vitreous opacities, and a general haziness which appeared to be due to the untransparent vitreous body. Through it, however, with the inverted image, could be seen numerous splotches in the choroid, and large atrophic crescents to the temporal side of both optic nerves. O. D. V. = $\frac{2}{3}$, O. S. V. = $\frac{2}{3}$. She selects concave glasses, but they do not improve her ability to distinguish the letters. She received potassium iodide and bromide, ãã gr. v, t. d. , smoked glasses, and a solution of homatropine to be instilled four times each day. Also a wash of boracic acid, and the tear ducts were syringed with the same solution on alternate days. In two weeks she volunteered the statement that her vision was much clearer, — V. = $\frac{3}{4}$? without glasses. Treatment was continued from November 10, 1884, to December 9, 1884. She then selected readily the following formula for glasses: O. D. — 2.75 c. ax. $105^\circ V = \frac{2}{3}$ —. O. S. — 2.25 c. ax. $75^\circ V = \frac{2}{3}$ +. The homatropine was then stopped, and the correcting glasses given, to be worn, except for near work. The potassium iodide was continued. A week later she received for reading O. D. + 2.75 c. ax. 15° , O. S. + .50 s. C + 2.25 c. ax. 165° .

August 28, 1888, Mrs. H. came by request. V. = $\frac{2}{3}$ with each eye. Has worn her glasses constantly with great satisfaction. The conjunctiva is healthy, the choroidal splotches and crescents remain, but active inflammatory processes have disappeared. There is no swelling of the lens, but the opaque spiculæ are as before described.

November, 1890, Mrs. H. returned, suffering from a relapse. V. had sunk to $\frac{1}{3}$, she was suffering from headache, aggravated by any attempt to use the eyes or by exposure to light, and was afflicted by marked insomnia. The caruncles were swollen, the conjunctiva of tarsi soaked in tears, the eyes being red and watery. She was greatly annoyed by constant "itching" of the lids. After reading for a few minutes the page blurred, and she was forced to desist. The anterior chamber was shallow, irides reacted sluggishly, and the ophthalmoscope afforded only a foggy view of the eye-ground. Through the dilated pupils, a fine web and a granular detritus could be seen with + 4 D., moving slightly to and fro with each movement of the eye. The lens was swollen, but no new opacities. The relapse had followed an attack of influenza, which had greatly depressed her general nutrition. She was much alarmed, since a sister had but recently suffered an unsuccessful operation for cataract, at the hands of a homœopathic surgeon, and a brother had just placed himself under my care for rapidly increasing opacity of the lens, associated with vitreous opacities, bad choroiditis and myopic

astigmatism. Under treatment by homatropine locally, rest and smoked glasses, and the internal administration of tonics and alteratives, the headache, insomnia and local inflammation slowly subsided once more, and the vision steadily improved until, in the following February, 1891, she was once more able to read the letters in xxx at 20° with some difficulty, and she was discharged from any active treatment, having for the past month used a wash of boracic acid and a weak solution of eserine locally.

Case 4.—Miss S., æt. 81, came complaining of failing vision, violent headaches, giddiness and nausea, which followed any protracted use of the eyes. She had used convex glasses for reading up to her 78th year, when she discovered that they were no longer needful. She had always been subject to attacks of headache, which she said made her eyes weak. O. D. V. = $\frac{1}{5}$, O. S. V. = $\frac{1}{2}$. Slightly improved by concave glasses, confusion letters miscalled T + ? Eyes red and watery, caruncles swollen, conjunctiva injected, pupils dilated, large medium under homatropine. Lens in both eyes is strongly refracting, nucleus steamy and plainly outlined. In extreme periphery of both opaque spiculæ are seen shooting toward the pole in both posterior and anterior cortex. All the conditions more advanced in right eye. There was a large conus embracing the temporal margin of the optic nerve, semi-atrophic at the nerve margin, and imperceptibly losing itself in less marked choroidal changes as the macular region was reached. There was a woolly eye-ground throughout, and in places advanced pigment absorption. In O. S. the same conditions were present. There was no albuminuria or glycosuria. She was placed upon syrup of hydriodic acid internally, boric acid wash and homatropine locally. In a week the headache was greatly alleviated, the external redness and irritation was much better. At the end of a month she had so far improved that she experienced no difficulty in selecting correcting glasses, O. D. — 1.50 \bigcirc — 1, \bigcirc ax. 105° V. $\frac{2}{30}$, O. S. — .50 \bigcirc ax. 30° V. $\frac{2}{30}$ dif. —. The vitreous haze had disappeared, the eye-ground was greatly improved, the anterior chamber was of normal depth, lenticular opacity unchanged. T. u. No headache. There are no changes in the lenticular opacity. She received her glasses for constant wear in October, 1890, and a suitable formula for reading. All went well until the following January, 1891, when she returned, suffering from dim vision, headache and insomnia, which she said was brought about by too constant use of the eyes in working over Christmas presents for her friends. Under the same treatment the symptoms subsided, but V. in O. D. had sunk to $\frac{2}{30}$, and there was a distinct increase in the number and size of spiculæ in the lens. In April, V. remained as before, $\frac{2}{30}$, O. S. $\frac{2}{30}$ with difficulty,

and the intraocular conditions were approaching a condition of health.

It is not my purpose to weary the Section with a report of cases, only so far as is needful to present the clinical picture I have in mind. It will be observed that in the foregoing cases, there is a distinct history of long standing eye trouble, either recognized as such, or obviously present as indicated by the asthenopic history. The cases brought forward are simply examples taken from a large group, and are not intended to carry weight by their numbers. In each case the inflammation of the external tunica and the chorooiditis were present. The results of treatment were very gratifying.

In my former paper, I presented a condensed statement of 64 cases of incipient cataract, hurriedly collated from my private case-books by Dr. Ring. In the preparation for the present paper, the deductions are based upon still other cases, taken from my private records, carefully tabulated by Dr. Carpenter, but do, not materially alter the results based upon the smaller number. In it, however, are included not only incipient but mature cataracts. It is obvious from this statement, that figures cannot accurately express the true state of affairs, *e. g.*, the table shows over 70 per cent. of demonstrable intraocular disease. Had it been possible to study the eye-ground in all cases, it is probable that this percentage would have been still higher, since it was rarely absent where such examination was possible. There was a distinct asthenopic history in 47 per cent. of all the cases, and refractive error in 70 per cent.

In closing this paper, I repeat the conclusions closing the former paper, since a further study and widening clinical experience have served to strengthen the conclusions there expressed:

"In the views here expressed we find additional argument favoring the great importance of carefully correcting the refractive defects in the eye, since they lie at the foundation of certain diseases which strike at the very root of the vital processes upon which the health of the eye depends. It would seem to justify, furthermore, the conclusion: That, *while opacity of the lens is a disease of advanced life, it does not, in all probability, depend upon senile change, but is originated in local pathological states involving the nutrition of the eye itself.* That hence, in the stage of incipency, it is amenable to treatment by such measures as are calculated to remove the choroidal disease upon which it depends. That if these deductions are true, we are justifiable in giving a more hopeful prognosis to many persons who apply for treatment with incipient cataract. That if treatment fails to arrest the progressive degeneration in the lens, by virtue of the treatment adopted, the eye will be in a better condition to submit to the trials of operative interference."

1422 Walnut St., Philadelphia.

HOW SHOULD CATARACT OPERATIONS BE PERFORMED?

Read in the Section of Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY JULIAN J. CHISOLM, M.D.,

PROFESSOR OF EYE AND EAR DISEASES IN THE UNIVERSITY OF MARYLAND, AND SURGEON-IN-CHIEF TO THE PRESBYTERIAN EYE, EAR AND THROAT CHARITY HOSPITAL OF BALTIMORE.

That the technique of cataract operations is the most important element in success, no ophthalmic surgeon questions. Every improved step in the removal of an opaque lens has advanced the percentage of cures, until failures are the very rare exception, to a generally acknowledged fact that cataract extractions, formerly so fatal to the eye, have become the most perfect of surgical procedures. As a young graduate I found myself in Paris, the pupil of the elder Desmarres, when cataract extraction was by no means a common operation because of its difficulties, its dangers and its frequent failures. The common cataract operation of my early professional life was couching, a procedure that most of the ophthalmic surgeons of the present day have never seen performed. As you know, it was the displacement of the opaque lens from its capsular bed in the vitreous chamber, so as to free the pupil and allow light to form pictures upon the retina. The immediate and momentary results of this operation were very brilliant. The staff needle was the magician's wand. With it the blind eye was apparently touched, and sight was instantly restored. In the twinkling of an eye, from seeing nothing, the patient could behold the face of the surgeon who had performed this miraculous cure, and would be loud in his expressions of gratitude. The operation bore success upon its very face, and was declared such to the admiring class of professional attendants. This was in the early days of Napoleon the Third, and in France chin beards were in favor. If the surgeon were ambidextrous, he would steady the head of the male patient firmly, holding the beard with one hand, while with the other he would plunge the needle into the temporal side of the eye, and make the point appear in the pupil from behind the iris. In a moment the lens would be forced out of its position, through hyaloid tissues, into the lower part of the vitreous chamber, where it would be left resting against the retina and ciliary border. By changing hands in case of double cataract, the other eye would be in like manner impaled, and the lens displaced from before the pupil. This performance was truly the *coup d'état* of the operating room. Two brilliant, successful operations for cataract would be scored. The lids were then closed by strips of black court-plaster, and the patient sent to the ward, from which only a limited number reappeared with sight. In a large number of those operated upon, painful inflammations would sooner or later set in, to the de-

struction of the vision which a momentary glimpse had promised to the patient.

At that time, when couching was of daily occurrence, I saw but very few extractions. The operation was deemed too serious for general application, and was rarely attempted by the most skilful. For it patients were selected and were carefully prepared by days of medication, and also days of training, so that the eyes could be kept quiet while the manual was being perfected with the broad knife. The patient was put to bed before the operation was commenced, and every precaution was used to avoid motion of the body during the whole bed treatment. The eyes were kept carefully bandaged for days. With all of these precautions, failures were so frequent as to deter many blind persons from accepting the ordeal. If every other eye turned out well, the successful surgeon was satisfied with his work, and was congratulated by his colleagues.

What great changes have been brought about in my personal experience! From the satisfaction of not losing more than 50 per cent. of eyes under cataract extraction, some at the present day feel unhappy if they lose a single eye out of a hundred cases of simple senile cataract operation. All of this the improved technique of the operation has accomplished. The ideal cataract extraction seems nearly attained by the methods now adopted. Asepsis and antisepsis have largely brought this about. To have absolutely clean instruments, as well as sharp ones, is a very important integral part of the work. There was a time in my early experience when every cataract patient had to be especially prepared by days of medication and dieting before they were made fit, or as we now see it, before they were made unfit, to undergo the operation of extraction. The instruments used were considered in good order provided there were no rust spots upon them. Our present knowledge, that invisible pathogenic germs introduced into wounds by bright instruments excite destructive inflammation; also that active purgation is not the universal panacea for reestablishing or maintaining health, has revolutionized the work of the ophthalmic surgeon. He now devotes more time to the purification of his instruments, his hands, and the eye to be operated upon, and less to the disturbance of the healthy natural condition of his patient. At the present time, most of my cataract extractions are made on the day that the patients present themselves for treatment. In hospital practice, they are sent from the free dispensary to the operating room, a warm bath in transit, for general cleansing purposes, being the only preparation made. My method of cleansing instruments is to plunge them into boiling water. I prefer this to soaking them in a carbolic or a boric acid solution. I find the boiling water the most speedy antiseptic or aseptic treat-

ment, without detriment to the cutting quality of the instruments. After the instillation of a 4 per cent. solution of cocaine for five minutes, I wash the eyeball with a stream of sublimate solution, 1-4,000, and attribute more benefit to the thorough cleansing of the conjunctival surface by water thrown from an irrigator than by the momentary action of the mercurial solution. I consider this more asepsis than antiseptis, and would place as much confidence in a stream of unmedicated water that had recently been sterilized by boiling.

A properly made wire speculum seems to me the ideal method of keeping the lids apart. The instrument should lie flat to the temple, and should make no pressure upon the eyeball. All eye specula by no means carry out these indications. Some use the speculum only to complete the corneal section. I prefer keeping it in place from the beginning to the end of the operation.

I also use the fixation forceps until the lens is extracted. I feel that the eye is safer by so doing. Some use the forceps only to aid in the corneal section, and trust to their control of the patient during the remaining and important steps of liberating the lens. This always seems to me a needless risk. With many patients the eye will involuntarily roll up suddenly at a most inopportune moment, when instruments are within the eye chamber. Unless extreme vigilance and great dexterity is used to anticipate these eye movements, serious injury to the eye will occur. As against this confidence in the patient's ability to keep the eye quiet, I find the judicious use of the fixation forceps a better guarantee against accident.

By nearly universal consent, the corneal wound is made under the upper lid, and is restricted to the clear cornea, although the puncture and counterpuncture are placed in the limbus, where the white sclerotic overlaps the clear cornea. This is done to give width to the opening. The long, narrow, sharp pointed and keen cutting knife of Graefe is in universal use. To do all that is expected of it requires the constant care of a good cutler. In making the section, most surgeons follow the corneal curvature in a line just within the clear corneal boundary. The varied size of the opening through which the lens is to escape without squeezing the angles of the corneal wound, is secured by approaching more or less to the horizontal meridian in the transfixion. This needs experience and judgment to determine in advance, in each case, the size of the lens to be extruded. In making the corneal section some cut with the point of the knife, and then with the heel—a sawing motion. Others complete the entire section by making the point follow the corneal curvature as the blade is pushed forward. These are peculiarities of the operator, and are non essential, provided the knife is

dextrously handled, and pressure is not made upon the iris by the blade of the knife in the to and fro movements of sawing. When an iridectomy is to be made, it is now generally agreed that the coloboma should be small. By seizing the iris near the pupillary border with the iris forceps, it is drawn vertically upwards. As soon as the pigmented pupillary edge is seen out of the corneal wound, this protruding portion of the iris is cut off by one snip of the scissors. This gives a comparatively small opening which will not be conspicuous, nor will it permit too much irregular refraction. The method of opening the capsule is still a mooted point. To tear off and take away the anterior surface of the capsule is undoubtedly the ideal method, as it does away with the secondary operations. With an iridectomy and a properly constructed forceps, this can be readily effected. When the iris is left intact, it requires nice manipulation to avoid including the iris in the blade of the forceps. In opening the capsule with the cystotome, much is said of the cutting properties of this diminutive blade, which seldom acts as a knife, but tears the capsule with its sharp point. Provided the rent is made large enough to let the lens out freely, it seems to matter little whether it be in triangular or in T shape. Either of these seems preferable to the horizontal cut over the upper edge of the lens, which leaves the anterior capsule to be disposed of by a secondary capsulotomy some weeks after the extraction. The delivery of the lens is made either by curette pressure on the cornea, or by finger pressure through the lids, the speculum being previously withdrawn. When the patient can be relied upon to direct his eye as the operator desires, no great difficulty presents for finger manipulation. I, with the majority of surgeons, prefer to retain the speculum until the pupil is cleared of all lens substance. I find that when the corneal wound has been made to correspond with the size of the lens to be extracted, the pressure of a shell spoon below the ciliary border tilts the upper edge of the lens forward as well as starts its movement upwards, and delivery is accomplished by following with the spoon the lens as it advances. In the majority of cases, by spoon manipulation on the cornea all lens substance can be removed, even when the iris is left intact. When the lens seems to stick to the inner face of the iris, I have found much benefit in making pressure with the fixation forceps above the corneal wound. Beside keeping the eye quiet, it helps to direct the upper edge of the lens through the corneal opening. To get out fragments of lens which are disposed to remain notwithstanding spoon pressure, I have sometimes used the curette, as is constantly done by Galezowski; or I have washed out the chamber, as is the constant practice of De Wecker. I do not find it necessary to use either of these methods habitu-

ally, as do those surgeons. I have found at times the forceps of great value in recovering fragments of thickened capsule. Recently, in one instance of capsule so thick that the effort of dividing it ruptured the suspensory ligament, I seized the capsule with forceps, and delivered the lens entire in capsule by traction. It was without iridectomy, and gave perfect final results. In another case, equally without iridectomy, with thick capsule which did not yield promptly to the cystotome, I drew out the entire capsule by forceps, and then by pressure removed the lens. There is no doubt but that a very important part of the ideal operation of cataract extraction is to leave the pupil clean of all lens detritus. This should be effected by patient, delicate manipulation, using curette, syringe or forceps, as the indication may demand. When iridectomy has been performed, it is important to have the angle of the corneal wound freed from the presence of any fold of iris, and the spud should be used to dislodge any portion of this membrane which may have been caught in the lips of the wound. When no iridectomy is done, in the majority of cases, after pupil cleansing, the iris resumes its normal position with round central pupil. Should the pupil be irregular, or the iris tend to prolapse, it should be replaced *in situ* by smoothing it out with the side of the spud, using gentle lateral pressure on the face of the iris in the anterior chamber to release any pinching of the iris by the angle of the corneal wound. If the iris be injured in the lens exit, or its tendency to prolapse shows itself, it would be better at once to convert the operation into one with iridectomy, rather than run the risk of an iritic hernia after the final dressing is made. The cleansing of the corneal wound of any blood clot, and the removal of all lens detritus from the conjunctiva, complete the operation. If no iridectomy has been practiced, a drop of an eserine solution, $\frac{1}{2}$ per cent. strength, is placed upon the cornea, otherwise the eye is ready for the permanent dressing. With the closing of the lids after a careful operation, at least nine-tenths of the dangers against a successful result have been already successfully met. In my professional experience it matters little how the eye is dressed, provided the upper lid be kept for a few days over the corneal wound, for its uniform support whilst healing, and provided no irregular pressure be made upon the cut eyeball by badly adjusted compresses, or by too tightly tied bandages. Experience has led me to adopt the lightest of dressing, and the avoidance of dark rooms. I feel also quite assured that we have all erred in inflicting too much bodily restraint, to the annoyance of our patients. To be sure, we get finally good eyes after carefully performed operations, when we keep patients in bed, on their backs in dark rooms; but we equally get good results in like proportion after carefully per-

formed operations, when we do not treat them as bed patients. It is more the careful technique, and not so much the after-treatment, that increases the percentage of cures. I am glad to say that I see a general relaxation from the rigid rules for dark rooms and bed confinement in such universal use a few years back. I am sure that this rational change is for the good of both surgeon and patient.

The ideal extraction of simple senile cataract is undoubtedly without iridectomy, making a flap opening in the upper segment of the clear cornea, destroying, or better, removing the anterior face of the capsule, and getting rid of all lens detritus from the pupil. The operation of extraction without iridectomy is evidently growing in favor. With myself it is decidedly so, as shown by my annual hospital reports. The report of work done at the Presbyterian Eye, Ear and Throat Hospital of Baltimore City for 1887, gives 83 cataract extractions, all with iridectomy. For 1888, 97 extractions of senile cataract, of which 40 were done with iridectomy and 57 without. For the year 1889, of 93 extractions, 33 were with iridectomy and 60 were without. For last year, 1890, of 113 extractions, 93 were without iridectomy, and only 20 with iridectomy. Unless especially contraindicated, all simple senile cataracts are extracted by me without iridectomy. When accidents occur to the iris during the corneal section, or during the escape of the lens, it may be proper to excise a portion. In some cases, when the iris is replaced after the lens has been extracted, it shows a tendency to prolapse, notwithstanding the instillation of eserine. Should such be noted, it is better to remove the protruding portion of iris, and in this way avoid the accidents of iritic hernia during the after-treatment.

PRESSURE ON THE GLOBE AFTER CATARACT EXTRACTION.

Read in the Section on Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C. May, 1891.

BY EDWARD JACKSON, A.M., M.D.,

PROFESSOR OF DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC, SURGEON TO WILL'S EYE HOSPITAL, ETC.

What is to be said under this head will also apply to all operations involving the section of the cornea or sclero-corneal junction; but is of greatest importance with reference to cataract extraction since it involves the most extensive of these sections.

In the normal eye the contents of the sclero-corneal coat press outward at every point with a force represented by a column of mercury about thirty millimetres in height; and the sclero-corneal coat at every point successfully withstands this pressure, by its own continuity and firm

structure. The instant a corneal section is made by the solution in the continuity of the coat its power of resisting outward pressure is annihilated. But as the same section also permits the contents of the globe to freely escape, the outward pressure is annihilated and thus a new and equally perfect equilibrium is established. My plea is that we shall respect this new equilibrium, and not destroy it by excess of external pressure.

At the close of a perfectly satisfactory cataract extraction, the lips of the corneal wound are held by the physical properties of the sclero-corneal coat in perfect apposition; the globe has its normal contour. If there is any deviation from this ideal condition it is always in the direction of deficient contents in the globe and tendency of the cornea to flatten or collapse. And if there be any tendency to gaping of the wound that tendency is due to distortion from sinking in of some other part of the sclero-corneal coat; the necessary manipulations of the globe having pressed out so large a proportion of its contents that the secreting tissues have not had time to replace it. And so long as the corneal section remains pervious, permitting the escape of the aqueous, it is impossible that the pressure in the anterior chamber should become excessive and cause any bulging of the section and adjoining tissue.

When, however, the lips of the wound have become adherent throughout their length; so that all escape of fluid through the wound is checked, and the aqueous is compelled to seek its normal channels, the tension of the globe, the outward pressure of its contents, rapidly rises toward the normal. But as yet the union of the lips of the wound, and the lips themselves, softened by the nutritive changes attending the healing process, are less able to withstand this pressure than the other parts of the sclero corneal coat, and they relatively yield before it in a local bulging. The appearance of this bulging is about the best evidence we have, that the wound has closed throughout its length.

This bulging of the cicatrix reaches its maximum in a very few days after its first appearance, usually within forty-eight hours; and from that time, if the tension of the eye be not sustained notably above the normal, it continues to diminish until it has entirely passed away, under the influence of normal cicatricial contraction of the scar. I have never seen permanent noticeable bulging, unless the iris were incarcerated in the wound, and in simple incarceration without prolapse it may disappear entirely. So much for the natural history of the scar after a cataract extraction. Let us approach the subject from another point of view.

In reporting some cases of glaucoma in which, after other operations, enucleation had been done and the globes subjected to careful study microscopically, before the meeting of the American

Ophthalmological Society in 1887, Dr. Wm. F. Norris says: "A study of the cicatrices of these operations (iridectomies and one cataract extraction) shows in each case a displacement of the relative position of the corneal flap and the corneal stump from which it was cut. In each instance the edge of the flap rides up a little, while the cut edge of the proximal portion of the cornea projects deeper into the anterior chamber. In comparing them with the beautiful and careful drawings of Becker in his "Atlas of the Pathological Topography of the Eye," we find that a large majority of his plates, representing flap operations with and without iridectomy, Graefe extractions and iridectomies, show a displacement of the cut edges in a corresponding manner, while two of them give examples of the end of flap being deeper in the anterior chamber, while the proximal edge of the cornea rises slightly above it. In a few instances only, are the inner edges of the incision nearly on the same level." Dr. Norris thinks: "These facts present good anatomical reasons for the utmost diligence on the part of the practitioner to prevent any undue motion of either the body or eyes of the patient after operations, until the wound is sufficiently closed by adherence of the cut surfaces to make it probable that it will not give way or be displaced."

Without questioning the correctness and importance of Dr. Norris' conclusion, it seems to me that the facts to which he draws attention, and his observations can be readily verified by inspection of the photographic reproductions of the appearances in question, give us even more definite indications as to the cause of displacement to be especially guarded against after cataract extraction.

In general the corneal incision in a cataract extraction is not perpendicular to the portion of the cornea through which it passes; but is so inclined that the oblique edge of the flap overlies the corresponding surface of the stump from which it has been cut, in such a way that if the parts are drawn asunder the overlapping will diminish, but if they are thrust together, the over-riding of the flap will be excessive, and only by displacement of very serious extent can the stump be made to over-ride the flap.

When, after the completion of a corneal section the intraocular tension is reduced to zero, the only resistance that is offered to external pressure on the globe is from the elasticity of the coats, tending to reproduce and preserve their normal shape, and this is as great as usual except at the point of incision where it has been for the time entirely destroyed.

Having these facts clearly in mind let us see what is, what necessarily must be, the effect of external pressure on the incised globe.

First, if the pressure be in excess over a limited

portion of the globe its tendency is to push in that part of the scleral or corneal coat, and secondarily there will be a tendency of the neighboring portions of the coat to tilt out. In the uninjured parts of the globe this tendency to tilting out is met and restrained by the inclination of all other parts of the coat to preserve their shape. But with the free edges of flap and stump this restraining influence is removed and a tilting out of the edge may result. Only under such conditions, or by the direct thrusting in of the free edge of the corneal flap, can the over-riding of the stump occur.

But even if external pressure be applied to the globe with practical uniformity, its results will be scarcely better. There being no intraocular tension, such pressure is resisted only by the resilience of the walls of the globe, and by those walls is transmitted as by a perfect arch, until it reaches the point at which the arch is broken by the corneal incision. Here the tendency is to force the two lips of the incision together, and the result is just such a displacement of the lips of the wound as has been found to occur in the large majority of such eyes examined, an over-riding of the flap upon the stump.

Probably the only reason that would be given for pressure on the globe after cataract extraction, at least by the majority of surgeons, would be that it would aid in securing the fixation and complete rest of the globe. The bandage may aid the fixation of the eye in three ways. By preventing the use of the eyes it removes the chief inducement to turn them from place. But for this purpose it is, of course, essential that both eyes be bandaged. Then the constant contact of a dressing with the lids probably exerts a very important reflex influence, restricting those movements of the eyes that are liable to be made in response to sounds from various directions, or in response to impressions made on other senses. Finally the bandage may, by pressure, mechanically resist the movement of the eye; though I believe it can never altogether prevent it. But the restraint of movement by the application of mechanical force to the globe does the very harm that restraint of movement is hoped to prevent. If, in spite of pressure, movement of the globe occurs beneath the bandage, no matter how evenly it is applied, the area of its application, and points of greatest force must vary with every movement of the globe. Pressure simply becomes a sort of massage. And if massage is to be applied, can it not be more rationally done than by the chance movements of the bandaged globe? It is thus evident that in the first stage of healing, until the wound is quite closed, pressure can only do harm. After the complete closing of the wound there is a distinct tendency to bulging, which pressure might be expected to somewhat counteract if it could be applied steadily to the

point of deficient resistance on the part of the coat, and to that point alone. But such use of pressure is manifestly impracticable.

To recapitulate. At the completion of a cataract extraction, or other operations involving a corneal section, an equilibrium without tension is established, while the resiliency of the sclero-corneal coat tends to keep the lips of the incision in the best possible apposition.

That pressure on the globe can only aid in fixing it by doing it mechanical violence, and by the ocular movements is transformed into a species of massage; and whether such pressure be uneven or uniform, it can only tend to cause the relative displacement of the edges of the wound.

Therefore, the primary consideration in the application of a dressing after such an operation is the avoidance of all pressure.

TO WHAT EXTENT ARE PERSONAL RESTRAINTS ESSENTIAL DURING HEALING OF CORNEAL WOUNDS.

Read before the Section of Ophthalmology of the American Medical Association, at its Meeting in Washington, D. C., May, 1891.

BY T. E. MURRELL, M.D.,
OF LITTLE ROCK, ARK.

It is still considered by the majority of ophthalmic surgeons that when the cornea has been extensively incised complete restraint of both eyes, and of the body as well, for some days is essential to safe and perfect healing. This applies to operations on iris or lens requiring opening of the aqueous chamber by a more or less extensive section. Furthermore, in compliance with this opinion, it is considered that such operations should be performed in the room the patient is to occupy in order that as little disturbance of person as possible shall be created. Based upon an individual experience now extending over four year's careful tests and observation, I feel authorized in entering a remonstrance against these iron-bound rules, and take this occasion to offer a plea for greater personal liberties to those subjected to iridectomy or cataract extraction.

It is true, very plausible arguments can be produced in defense of the prevalent custom of bandages, darkened rooms and confinement in bed, but one solitary fact is worth a hundred theories, and experience and observation must always take precedence of abstract reasoning. The restraints ordinarily put upon those who have submitted to an extraction of the lens are often very trying, especially to the aged, the depressing effects of which doubtless often cause tardy healing of the wound. So much do some persons dread confinement in the dark and exclusion of both eyes from sight that under such methods I have sometimes found it very difficult to get the patient's consent

to submit to an operation on the second eye, especially if satisfactory vision has been obtained in the first. But with the very slight restraint I now put upon my patients they regard the operation for cataract and the after treatment as a trivial matter in so far as personal discomfort is concerned.

I had already begun to draw the reins more loosely as regards the points at issue when I became acquainted with Dr. Michell and his methods. I was so impressed with the simplicity as well as philosophy of his dressing and management of his operated cases that I at once adopted his methods, and for a period of four years have used no other.

His statement that he made simple iridectomy an office operation was a surprise to me, but I received it with confidence, and after thorough trial became so convinced of its entire safety that I now no more hesitate to perform an iridectomy in my office, and let the patient walk or ride home than I would to make a paracentesis of the cornea.

Dr. Michell was much more cautious, however, with his extractions, whom he confined to bed a number of days. It occurred to me if the stringent rules I had hitherto followed with my iridectomy cases, which were managed with almost as much caution as an extraction, were unnecessary, then they were likewise, perhaps, to a large extent at least, unnecessary in the latter also. At any rate I determined to make a test of it. I had been in the habit of taking the medical class of our college with me to the room where the patient was to remain, often in distant parts of the city—we then having no satisfactory hospital arrangements—to witness operations for cataract. The next case that applied for relief, I performed the operation in the college building and sent the patient, an old negro man, home, a mile and a half, in an express wagon. The case did as nicely as any I ever had. Encouraged by this I repeated it over and over again with like satisfactory results, leaving to the patients to get home in any manner they could, they sometimes walking a mile or two, always having an attendant. In no instance was there any irregularity in the progress of the cases that I could attribute to this cause.

I had considerable misgivings, however, on one occasion when, during an extraction, a good deal of fluid vitreous was lost. I feared that with only a strip of adhesive plaster over the lids and the patient going more than a mile to his home the balance of the vitreous would run out. But it was not the case. There was no more lost after dressing the eye, healing was by primary union and the result was quite satisfactory.

With such experiences as these, I felt warranted in taking like liberties in my private practice. About this time Dr. Cheatham published a re-

port of cases operated at the medical college and sent home to different parts of the city, all of whom did well.

Dr. Chisolm also made known the fact that he was in the habit of operating in a room downstairs and requiring his patients to walk up-stairs to their room, and that he had seen no harm from it. He furthermore took the initiative in leaving the unoperated eye free, a great pleasure to the patient, and not attended by any bad results. With such corroborative testimony I no longer hesitated to boldly operate in my office on any and all cases that applied, sending them to their homes or boarding houses afterwards. It was with some misgivings that I first tried leaving the unoperated eye open, especially if it had fair vision, on the principle that one eye cannot move without associated movements of the other. Trial of this convinced me in time that it was safe, and I now very rarely close both eyes. Owing to the better facilities to be had in a specially prepared office, and the more readily obtained assistance, besides the greater convenience and saving of time to the surgeon, there is a great gain in performing all operations in ones office. For two years past I have required all my iridectomy and cataract cases, as well as all others, to come to my office for operation, unless, as only occasionally happens, the patient, or family, insists that the operation be done at home. After an iridectomy or extraction only the operated eye is closed by a strip of isinglass plaster, and the patient is sent home in a carriage, or in a street car, or if not very far is allowed to walk home, being always accompanied by another person. He is instructed when he gets home to lie down or sit up as he may prefer, but to keep quiet, and to remain in his room, and not to use the unobscured eye except for some particular necessity, that is, he is not to attempt to read or use it unduly. I find but little disposition on the part of most persons to abuse these privileges.

It will occasionally happen, however, that they do, just as unruly patients will sometimes tear off the bandages.

I made an extraction in my office last winter on an old lady and sent her home, leaving the unoperated eye, which had quite good vision, free and with which she saw her way home. When I called to see her the next day she was not in her room but was in another part of the house quite busy about her domestic duties. She informed me she had been thus engaged from the time she got home from my office and was innocent of there being any harm in it. I at once enjoined her not to attempt the like again, and to remain in her room. Fortunately no harm came from her indiscretion. While such imprudence might lead to dire results, at the same time several similar instances have taught me that there is a great deal of unnecessary fear of

any and all personal liberties after important operations on the eye, that for cataract in particular.

The great secret, in my opinion, lies in a well performed operation in a properly selected case, then closing the lids naturally over the globe and retaining them there by the simplest means, and molesting the eye as little as possible until union of the corneal section has taken place and all will have been done that it is in the power of the surgeon to do to aid Nature in her efforts at repair. As to confinement in bed, the exclusion of light, closely confining both eyes, and any and all personal restraints that bring discomfort, they play no important part in the final results and are both cruel to the patient and useless.

While allowing my patients these greater liberties and additional comforts I have at the same time seen no unsatisfactory results that could in any way be attributed to them.

In fact I have had fewer complications after extraction since doing them in my office than ever before in my experience.

I feel confident that a fair and reasonable trial of the methods I have here described will convince any one that they are not only safe, but that he will be greatly pleased with the convenience and satisfaction they will afford him, while he will have added the gratitude and appreciation of his patients for converting such hitherto formidable operations into seemingly simple ones.

REMARKS ON THE NEED OF MORE EFFICIENT PROTECTION OF THE EYE AFTER CATARACT EX- TRACTION, AND AN IM- PROVED APPARATUS FOR THE PURPOSE.

Read in the Section of Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 5 S, 1891.

BY G. E. FROTHINGHAM, M.D.,
OF DETROIT, MICH.

Perfect coaptation and support of the corneal flaps, freedom from any form of pressure that may cause gaping of the lips, or reopening of the wound, and perfect rest of the eye, are the objects mainly in view in adopting any form of dressing after the extraction of cataract. That any imperfect coaptation, or motion of the lips of the wound will interfere with its speedy and perfect union, and, that every reopening of the wound retards recovery and subjects the eye to dangers from infection and inflammatory reaction, are propositions so axiomatic that no one will dispute them. They seem to be universally received principles, though in practice we hardly take the precautions we ought to observe in

order to secure our patients against these sources of danger. Mackenzie in his chapter on the after-treatment of extraction, writes as follows:

"A careful assistant or experienced nurse, sitting constantly by the bedside for the first forty-eight hours, and for several succeeding nights, ought to attentively watch the patient when he wakes, and taking care especially, that he does not turn round suddenly upon the eye which has been cut or put up his hand to rub it. If there is any particular reason to dread the latter accident, it may be proper to muffle the patient's hands and pin them down by his sides.

"The length of time during which the patient is to be kept in bed, is a point upon which there has been a wide diversity of practice. It would appear that Wenzel was at one time in the habit of confining his patients to their backs, without change of posture for a fortnight or three weeks, but that afterwards he shortened the period of confinement to eight or ten days. Mr. Phipps, on the other hand, examined the eyes on the morning after the operation, applied a shade and allowed the patient to rise.¹ A middle course appears to be the most judicious. The incision may be looked at the third day. On the fourth day the patient may be allowed to sit up for a short time. On the fifth the eye may be fairly examined, but immediately afterward covered with a shade. In eight or ten days the patient may be allowed to look at large objects and look about the room."²

Lawrence says: "The coverings of the eye should be light; a soft rag doubled and wetted in water, may be gently bound on the eye by a single narrow linen band, and the other may be covered in the same way. Recollect that the eye is naturally open to the air, and that a sound eye would be heated and rendered uneasy if it were bandaged up.

"The method followed by Beer and most of the German operators, of closing the lids by a strip of sticking plaster carried from the forehead to the cheek seems to me most objectionable.

"We must not, therefore, regard it as a rule, that the patient is to be bandaged. The light covering I have recommended is rather employed to keep the eye quiet, and guard it from any slight accident, than as a measure absolutely necessary; on the latter account it is proper to have the eye covered during the night, but it may be left open, or at least with thin wet rags only on it when the patient is awake."³

This open method of treatment seems to have been quite common until von Graefe advocated the use of the pressure bandage in connection

¹ On the Treatment of Patients after the Operation of Cataract, by Jonathan Wathel Phipps. London. 1792.

² Diseases of the Eye, by William Mackenzie, Edition of 1833. Boston, Carter, Hendee & Co.

³ A Treatise on the Disease of the Eye, by W. Lawrence, F.R.S. London, 1833. 1p. 425 and 426.

with the operation he devised, and which soon became so general.

We are to day debating the same questions that divided the colleagues of Lawrence and Mackenzie. While we do not direct that a faithful assistant or nurse watch continuously by the bedside for two whole days and several succeeding nights to see that no injury is inflicted upon the eye, we may sometimes wish we had.

As it was more than a century ago with the followers of Wenzel and Phipps, so to day we have practically two methods of dressing the eye after cataract extraction.

By one method the lids are kept closed by the application of a cushion of absorbent cotton, charpie, or common cotton, held in place by a protective bandage. This may be applied lightly according to the directions of Stellwag and other writers, or with quite firm pressure, as advised by Graefe, and still preferred by some.

By the other method of dressing the lids are held together by strips of adhesive plaster, the eye being otherwise left free from covering or pressure. This is what is now known as the open method, and is advocated by several members of this Section.

I think it will be conceded that each of these methods has some advantage which the other does not offer, and also that neither fulfils all the indications that we attempt to meet by the dressings we adopt after an extraction.

I think it will also be quite generally admitted that the closed lid, with no artificial pressure, constitutes the best and safest splint for holding the lips of the wound in coaptation after the operation, and that the closing of the lids of both eyes conduces to that perfect rest of the operated eye essential to its greatest safety.

There are many who believe it nearly, if not quite, impossible to apply a bandage with that firmness necessary to maintain its position, without exercising unequal pressure upon the eyeball, sufficient, at times, to interfere with speedy healing of the wound and reëstablishment of the anterior chamber. If the bandage should happen to slip in any way, either from below upward, from above downwards, or from side to side, this unequal pressure is almost sure to be produced, and such accident is not unfrequently the evident cause of reopening of the wound. The method of dressing the eye with large pads of cotton and a pressure bandage has been retained partly with a view of protecting the eye from slight blows, which might prove more harmful in the open method of dressing. That the pad and bandage, though it affords some protection from slight blows, can offer no sufficient resistance to severe blows, is too evident to need discussion.

It has always been my custom to apply with great care the usual pad and bandage, to guard against its slipping by a second bandage of thin

material applied by several turns outside of the first bandage, and passing under the chin and over the vertex, and finally fastening the two securely together, so as to prevent any motion of that part of the original bandage which covers the eyes. To guard against blows I have impressed the assistants with the necessity of great caution in their manipulation, and during sleep have had the patients hands so secured, that while a certain degree of motion was allowed, there was no possibility of getting them up to the eye so as to rub or strike it.

Notwithstanding these precautions several accidents have happened that have impressed me with the need of more efficient means of protection than are in common use, and with the necessity of having such appliance cause so little annoyance to the patient, that they may be willingly tolerated until the wound has had time to become very firmly healed.

A brief account of a few accidents that have happened to my patients will serve to illustrate the nature and extent of the danger against which we ought to provide better protection.

Case 1.—A lady of 55 was operated upon by me for cataract of the left eye, by the old method of simple extraction with Beer's knife. Operation smooth. On the third day the eye was opened. The anterior chamber was restored, the pupil was clear and central, and vision seemed good. On the fourth and fifth days the eye was examined and showed no sign of complication. On the morning of the sixth day, after the eye had been dressed, she suddenly pitched her head forward with considerable force, and struck the operated eye against a chair post. The wound was reopened, the iris prolapsed, and the anterior chamber filled with blood. Although the prolapsed iris was excised and proper care instituted, inflammatory reaction resulted, a secondary operation became necessary and ultimate vision was only $\frac{1}{200}$, where a perfect result seemed almost certain before the accident.

Case 2.—A man, æt. 54, was operated upon for hard cataract of the left eye by Graefe's modified linear operation. The operation was smooth, and the eye was dressed in the usual way with a pad and bandage, and at night the hands were firmly secured to prevent his rubbing or striking the eye while asleep. On the fourth day the eye was examined. The wound was closed, pupil clear, and the eye free from inflammatory or other complications. On the 5th, the eye was dressed and examined, and everything was progressing favorably. On the fifth night the patient had his hands left free without authority. Toward morning the patient was awakened from his sleep by a severe blow upon the operated eye, which he had inflicted upon himself by bringing his hand violently against it. The pain was so severe that I was sent for and visited him at an

early hour. The wound was torn open and the anterior chamber was filled with blood, a clot of which protruded between the lips of the corneal incision. The blood was evacuated as completely as practicable, and the eye carefully dressed. Iritis supervened. A quite thick membrane formed in the pupil, and a secondary operation became necessary. The ultimate vision, fortunately, was good, being $\frac{2}{30}$.

Case 3.—A man, æt. 75, was operated upon by Graefe's method for extraction of cataract of right eye. The operation was smooth and the eye dressed as usual with pad and bandage and hands secured during sleep. On the fourth day the eye was examined. The wound had united, the pupil was clear and the eye free from redness. On the fourth night the patient turned suddenly on his face, struck his eye forcibly against the pillow, causing great pain. On examination of the eye it was found that the wound had been opened, the anterior chamber was found empty, and the dressings found wet and slightly stained with blood. Dressings were re-applied, and extreme caution urged against further injuries. On the sixth day the wound, which had again united sufficiently to hold the aqueous and restore the anterior chamber, was broken open by the patient while awake. He was sitting in a chair, and, in a state of reverie, suddenly brought his hand to his face, striking his eye with such force as to again re-open the wound. The pain caused by the blow was so intense at first, and the effect of the injury was so great that he nearly fainted. Again the wound united, but with a reddened condition of the eye, and an aggravation of the tenderness, which had existed, to a slight degree, ever since the first blow. On the third day after the second injury, although the attendant tried to watch the patient with great care, he struck the eye again with his hand in a manner similar to that which had caused the second injury, and for the third time re-opening the wound. As a result, a low form of iridocyclitis followed, retarding recovery and ultimately leading to detachment of the retina. The latter result would not have followed, probably, had the patient not wilfully disobeyed instructions and used his eye sooner than he ought to have done under the circumstances.

These are the extreme cases that have occurred in my practice, and I presume that like cases have occurred to most operators, and that slight injuries have quite frequently occurred. They demonstrate that the ordinary pad of cotton and bandage afford but little if any more protection against severe blows, than the open method. Neither can such accidents be guarded against by pinioning the hands of the patient by the side, since he may suddenly turn, as did my patient, upon his face, and produce the injury. Nor can the "careful assistant or trained nurse,"

recommended by Mackenzie and others, prevent them, unless they keep their hands constantly upon the arms of the patient. If they fail to do this, the movement of the patient may be so sudden and rapid that the injury will be done before an attendant can catch and restrain him. Pinioning the hands of the patient becomes so irksome that few will tolerate it and they will loosen their hands and get their attendants to omit the precaution after enduring it for one or two nights.

It would seem that the attention of the profession has not been turned to this subject as much as its importance really demands, for though only an occasional loss of an eye may follow from these injuries, to guard against *any* loss is the object of the prudent practitioner.

Within the last few months two communications on this subject have been made to the profession. The first of these was by Dr. H. Gifford, of Omaha, and appeared in the *Archives of Ophthalmology*, Vol. 19, p. 42. Dr. Gifford proposes to cover both of the eyes with "concave shields of stiff pasteboard, of such shape that the flaring edges may rest upon the bridge of the nose, the forehead and the cheek, while the arched centre is an inch or more from the eyeball. This is kept in place by an elastic band, but over all, to secure firmness, a monocular roller bandage covers that shield which is placed over the operated eye. Dr. Gifford's shield is easily made, and when firmly and securely applied, must offer quite complete protection from the kind of accidents I have mentioned, unless the shield should happen to slip from its place. In that case its edges very likely would take such a direction that one of them would press upon the eyeball. Under this shield the lids may be closed by adhesive plaster, or confined with the ordinary pad and bandage.

The objection to this shield is, that it is even more impervious and heating to the eye than the ordinary bandage, and this is a sufficient consideration to lead some operators to reject it altogether. To remove this objection Dr. J. S. Prout,⁴ of Brooklyn, has proposed a wire mask, made of wire netting such as is used for window screens, and fastened about the head by means of two tapes.

In remedying one defect and offering a covering which is light and cool, he proposed a form of dressing which evidently must be unsafe on two accounts. In the first place, it can hardly be held securely in place by the fastenings he proposes. Secondly, and mainly, it is, and must be, inefficient, by reason of the lack of stiffness, as a protection against the severe blows that are sometimes accidentally received by the operated eye, and against which Dr. Gifford's shield does offer protection. Again, an ordinary wire

⁴ The American Journal of Ophthalmology, January, 1891, p. 1.

netting cannot, even when sufficiently firm, be properly arched by any process to remain as a permanent firm concave surface, an inch or so removed from the surface of the lids. A consideration of the desirability of a dressing that, while cool and allowing free access of air to the eye, yet would be firm enough to resist severe blows, and so secured as to remain in place when applied to the most restless and unruly patients, led me to devise the mask which I here present. This mask is woven by a skilled wire worker, after a pattern which I furnished. By its construction the arch is so firm that a powerful blow cannot indent it, so as to allow of pressure upon the eyeball over which it is applied. It is open and cool. It is fastened in such a way that the tapes cannot slip over the vertex of the head or in any other direction, and allow the mask to become displaced. It is so formed, that should it become displaced, the edges would not strike against the lids, but be carried away from the eyeball. It can be used over any form of dressing. The open method may be followed and the patient allowed to use the unoperated eye if his attendant so desires, or it can be applied over a light pad of cotton, or the pad and bandage both, as the operator may choose.

While by no means perfect, I present it for the consideration of the Section, believing it to be the coolest and the most efficient of any dressing I have seen proposed, for protecting the eye from mechanical injury after extraction of the cataract, or while undergoing treatment for wounds of the eyeball, that might be re-opened by accidental blows or pressure.

DISCUSSION ON CATARACT.

DR. F. C. HOTZ, speaking of the management of cataract cases after the operation, said that whatever different views we might have on this point, we certainly all admit that the final success does not solely depend on a skilful operation, but also on the quick and smooth healing of the wound, and that therefore we are anxious to attain a speedy union of the wound. The necessary condition for first union of any wound is the accurate and undisturbed coaptation of its edges; and all our care and dressings after an operation must have this end in view, to wit: to protect the nicely apposed edges of the wound against any sudden or repeated disturbance. This end can be attained only if we keep *both* eyes closed until the edges of the wound are united. When the operated eye alone is closed, it is of course compelled, by the law of associated muscular action, to follow all the rotations of the other eye. These movements in the act of seeing are quick, and almost incessant; every such movement means a sudden tension upon the sclera by quick muscular contraction; and if the portion of the sclera thus acted on lies in the line of the

operation (as it does in up and down rotations), this sudden muscular tension will necessarily pull the edges of the wound apart. That this does actually occur, is shown by the sharp pain most patients experience, and the discharge of the aqueous humor we can see, when such rotations are made a short time after the operation.

Another factor likewise disturbing the rest and coaptation of the wound edges, is the winking. Every time the seeing eye winks, the orbicularis of the closed eye acts in association with its fellow, and makes a sudden pressure through the eyelid upon the globe. Dr. Jackson has just shown us how any sudden pressure upon the cornea, after an operation, will displace the wound edges; and the great discomfort patients experience under these circumstances, confirms it.

Now as to the materials used for dressing, I prefer the absorbent cotton and roller bandage of mosquito netting to the plaster or any other dressing. The cotton, carefully adjusted, forms an elastic cushion which readily adapts itself to the uneven surface of the eyelids. The roller is applied wet, and when the several layers get dry, they are so firmly pasted together that the bandage cannot get out of order; turning the head on the pillow does not affect it, and consequently the cotton under it remains absolutely undisturbed, and you will find it so when you remove the bandage on the second or third day. The object of the bandage is to keep the eyelids closed gently, just as in sleep; its object is not and cannot be to render the eyeball immobile. It is neither necessary nor could it be done by any degree of pressure; and any bandage which presses is objectionable.

Plaster strips I found very unsatisfactory; they would get loosened by the tears and separated from the lower lid, either altogether, or at least so much as to allow a partial opening of the eye; or they became so dry and hard that their stiffness made the patients very uncomfortable; they begged me to take them off. I was therefore much interested in seeing the working of these plaster strips in the hands of the most enthusiastic advocates of Michel's method. A visit yesterday to the Presbyterian Eye and Ear Infirmary in Baltimore, showed me that bandages were not altogether discarded (as we were led to believe), and that eyes would get as red and irritable under the plaster as I have ever seen them under the bandage.

And this is another untenable charge made against the bandage by the friends of Dr. Michel's method: that the bandages cause redness and photophobia. It is not the bandage or any other kind of dressing that does it, but it is the different degree of sensitiveness with which different eyes respond to an operation. While one eye opens up fully and shows no redness when the first bandage is taken off, on the second or third day,

another eye shows a moderate injection, and a third one shows a great deal of it, although the operation in all cases was alike. And while one eye may go without any dressing after the third day, I have seen eyes which required a bandage for several weeks, because when it was left off the eye became red, watery and painful, and all these symptoms disappeared as soon as the bandage was reapplied. Mr. Chairman, our forefathers in ophthalmic surgery may have been over-cautious, and enforced restraints (like absolute confinement to dark room and bed) which are unnecessary; but when we hear people talk as though an eye after an operation required no care, I believe it is time to call a halt to this tendency of going to the opposite extreme. Though I do not doubt that eyes may get well under this loose management, I insist that there are certain indications which must not be neglected, if we wish to call our management a careful and rational one.

DR. J. L. THOMPSON: As to the causation of non traumatic cataract, many interesting points present themselves. Heredity seems to have a marked influence. I have seen families apparently in robust health, where father or mother has been reported cataractors at a certain age, and where several of the sons and daughters have been operated on for same complaint, where no point of departure from health has been recognized even after careful examination of urine and other suggestive examinations has been made. My records, running over nineteen years, are very full of pencil sketches of incipient cataract. Often have I examined patients for anomalies of refraction, or other eye affection, where no trace whatever of lenticular opacity has been seen, and again in a year or two I have found the periphery or the nucleus slightly clouded. In some of these (the peripheral variety) both lens have been ready for operation in six months, others not in as many years, while others have not changed one particle after the lapse of sixteen years; especially is this the case where the opacity is at the lower inner periphery of the lens. Indeed I have seen hundreds of cases of opacity of this part of the lens which have never advanced after the first deposit or cloudiness.

Why is it that opacity of the lens takes place so often at the lower inner portion? Has gravitation, or lid pressure, or convergence, or efforts of accommodation any thing to do with these phenomena? Another symptom which has frequently arrested my attention while watching the progress of cataract is, congestion of the fundus manifested by floating bodies in the vitreous, and when we have the opportunity of watching these cases to the end often do we see the change from high degrees of hyperopia to the myopic condition. And here we often see the "second sight" of the elderly, again watch

these cases until after the opacity is greater, and the case is almost ready for an operation and the patient can hardly see to go about, when he calls upon us with a beaming countenance, seeing better than for years, the lens having fallen below the pupil. And again, to further astonish me, in one of my patients whom I had watched for years, and in whom I made a preliminary iridectomy five years before owing to a trembling lens, a more remarkable occurrence took place. Not having seen him for several years, he reported one day with the lens substance clear, and nothing but a little dotted capsule left. This occurred several years ago, and he now drives out and does his business with ordinary cataract glasses. So we cannot say cataract is incurable short of operative means. As to bandages, I cannot speak positively. Dr. Knapp, who is extremely careful to bandage his eyes after cataract operation, loses only one case in a hundred, while Dr. Chisolm, who discards bandages, gets about the same result. I think, however, a Providence favors Dr. Chisolm that would not me, for surely a Nemesis would overshadow me were I to try it. Since visiting Dr. Chisolm's Infirmary, a year and a half ago, I have used adhesive strips. I was surprised while there to see the freedom he allowed his cataract patients who were wallowing around on the beds and everywhere.

DR. P. D. KEYSER: There is now no doubt that the choicest and best operation for the extraction of cataract is that without iridectomy, but at the same time it cannot be made in every case. There is one condition in which I invariably make an iridectomy, and that is where the iris fails to respond promptly to light, or reacts sluggishly to atropia. In such cases I have invariably found iritis to follow the simple operation. There are many cases in which it is necessary to make an iridectomy twenty-four or thirty-six hours after the extraction on account of prolapse of the iris. In case of prolapse soon after the operation, iridectomy should not be made at once, for by instilling a drop of eserine solution in the eye every five or ten minutes for a half to one hour, the iris will sometimes be drawn in and the operation avoided. I have found washing out the anterior by means of Wecker's syringe, will remove much of any soft cortical matter remaining behind. In some cases I introduce the nozzle under the iris and wash out behind the iris. Where no iridectomy is made I follow Wecker in using a weak solution of eserine and boric acid in the syringe. The opening of the capsule is a particular point, especially where the iris is not cut. The instruments recommended for removing a piece of the capsule are apt to catch the iris and draw it out without extreme care. I find it impossible to cut a triangular piece out with the cystotome.

When the capsule is slit once the cystotome will not cut across it, but instead it is rolled or dragged back, and in a day or two falls back and closes the opening, requiring a second operation. My best success has been in passing the cystotome through the corneal incision and cutting the capsule across as near the upper periphery under the iris as possible; then turning the instrument with the fleam on the flat, and passing it under the iris opposite the first cut, the point of the fleam is turned downwards, and a straight cut made towards the centre of the first cut, at right angles to it, like an inverted T.

As to bandages, I believe that both eyes should be kept perfectly quiet for twenty-four hours by bandages, and the patient kept in bed for that length of time. I apply a little cotton on the eyes, and a Liebreich bandage for the first day; on the second day I let the unoperated eye out and the patient up. Plasters I do not like, as they are liable to come loose where court plaster is used, or to be painful on removing if adhesive plaster is used, and to cause a spasm of the facial muscles and pressure on the eye, with possibly, opening of the corneal wound. The bandage should be light and merely sufficient to hold the lids in normal apposition.

DR. EUGENE SMITH: "Why do we in simple extraction so often get prolapse?" He attributes it to tilting the knife forward in finishing the section, the upper part of the wound remains open and the aqueous leaks out for some time; but if the section is finished without tilting the knife forward so as to make a flap, the wound more readily closes, and there is less danger of prolapse of the iris. Leaves the mode of dressing to each one's experience. He thinks a little absorbent cotton on the eye held in place by strips of adhesive plaster from the forehead to the cheek very good, but prefers the bandage.

In opening the capsule, the tearing out of the central portion as first suggested by Græfe is difficult with any instrument hitherto constructed. He, however, had devised a forceps for removing a piece of the capsule which worked very nicely. It is like an ordinary iris forceps with the teeth on the lower side, quite long and projecting and extending some distance from the point.

DR. CHISOLM said he made an extraction without iridectomy about a week ago and the corneal wound had not yet healed. The cornea remained perfectly clear and there was no inflammatory reaction whatever about the eye. As to his methods he was only gratified with his present results compared with his former under the old methods.

DR. AYERS now uses adhesive strips exclusively in dressing the eye after extraction. He thinks much depends on their careful application.

He is careful that the strips are not long enough to pass beyond the width of the lids. In this all traction by adjacent muscles, especially of the orbicularis, is obviated.

The extraction is made without the use of a speculum, the assistant holding the lids open with his fingers. The decision of the capsule is made before the lids are closed. The lids are then closed for a moment, after opening the eye and directing the patient to turn his eye down, pressure with the point of the index finger, or with the curette until the lens presents itself and is completely delivered.

DR. DUDLEY S. REYNOLDS said: I agree with those who are particular to secure a section with beveled edges to favor coaptation in the wound. I am anxious to add my endorsement of the lightest possible dressing without bandage, not to be removed or in any way disturbed for four or five days, unless evidences of irritation occur. As to prolapse of the iris, I have to say it may nearly always be prevented by the free use of eserine in solution before closing the eye.

I would not regard iridectomy as justifiable, excepting as stated by Prof. Keyser, where iritis has been present.

DR. SAVAGE: There are, to my mind, two indications for iridectomy in cataract operations. To one of these Dr. Keyser has already referred, viz.: when the pupil will not dilate. The other indication is when the cornea is flabby. In this condition, my experience teaches me that if an iridectomy is not done, there will be prolapse in spite of eserine.

DR. RANDALL wished to add his testimony to the importance of treating with alternatives the cases of incipient cataract, as he had seen many cases of prompt cessation of all advance in the cataractous process, which had before seemed rapidly progressive. Opacities are generally first and most markedly seen down and in, because this is the worst part of the choroid, being the most exposed to excess of light. These have not seemed any less apt to advance than spicules in other parts of the lens. The media have become clearer and so remained, and there has been generally little increase of the swelling of the lens, which has at times been previously marked.

DR. MINNEY: In his experience, a fluid vitreous is also an indication for iridectomy, in addition to the one mentioned by Dr. Keyser, of iritis, and the flabby cornea alluded to by Dr. Savage.

BOGUS MEDICAL DIPLOMAS.—The Wisconsin State Medical Board says the Northwest is being flooded with fraudulent medical diplomas, purporting to be issued by the University of Victoria, at Montreal. Fifty of these diplomas have been found in Wisconsin and South Dakota.

THE REFORMED NUMERATION OF PRISMS AND THE CENTRAD AS THE UNIT.

Read in the Section of Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY B. ALEX. RANDALL, A.M., M.D.,

OPHTHALMIC AND AURAL SURGEON TO THE CHILDREN'S HOSPITAL;
PROFESSOR OF OTOTOLOGY IN THE UNIVERSITY OF PENNSYLVANIA
AND THE PHILADELPHIA POLYCLINIC.

About twenty years ago was inaugurated the reform in the numbering of ophthalmological lenses upon the basis of their actual strength as determined by their focal length. Before that time lenses were generally taken at a face value, which represented, in such diverse units of length as were locally employed, the radius of curvature to which each was ground. The reform met opposition on the ground that lenses had to be made by grinding to surfaces of given radii, that the radii gave a sufficiently accurate indication of the focal strength, that there would be large financial loss in abandoning the old system and adopting the new, with its less familiar units—in short, that the change, even if theoretically desirable, involved more practical difficulty than actual advantage. Yet the positive advantages of the reformed system, arising in part from its metric character, but also largely from its acknowledged accuracy of basis, carried it in the face of all opposition; and its acceptance is now nearly universal. It was clearly essential that we should consider lenses from the side of the user, not of the maker; and that we should call for lenses of given strength, and leave to the optician the matter of the refractive index of his material and the radii to which he should grind it. Doubtless lenses were long ground upon old inch moulds, but these have now been tried to metric accuracy or else replaced; and aside from that, it is doubtful if any of the opticians would now elect to go back to the older system.

As with lenses, so too with prisms, the same principle holds good; and it is to be regretted that it was not seen at the time, that their numeration stood in need of the same reform. We use prisms to measure or correct deviations of the optic axes, because they have the property of bending the rays of light passing through them. We employ them to obtain a certain effect—a deviation of the rays of light—and are wholly unconcerned as to how that deviation is secured. In the past we accepted prisms as furnished by the optician, and numbered in accordance with the angle between the two faces—this being the basis upon which they were more or less accurately ground. Only the few took into consideration the actual strength; and these were satisfied with the fact that the deviation produced approximated the half of the refracting angle, just as the radius of curvature gave an approximation

to the strength of a lens. Yet this relation is far from constant for prisms of varying strength, even if accurately ground and of identical material; and in practice the oculist generally depended upon the method of neutralization by means of the prisms of his test-case. Yet, convenient as that method is and will always be, it leaves one entirely at the mercy of the numerous errors which Dr. Jackson has shown to be so common in the test-sets; and we must have, as the basis of our system of prism numbering, a method of exactly measuring the effect—the deviating power—of each prism.

Such a system was proposed by Dr. Edward Jackson, to whom belongs the honor of instituting the reform and demonstrating its necessity. He proposed that prisms be numbered according to the actual deviation in degrees which they cause in a ray of light passing through in the position of minimum deviation. Just as a lens has a varying strength when it is tilted, so has a prism one position—that when the entering and emerging rays make equal angles with its faces—where its deflection is at its least—to increase with any tilting in either direction. This, or some other equally definite position, must be accepted as the one in which the deviating effect shall be measured. So placed, a prism causes a definite angular deviation; and the size of this angle measures the exact strength of the prism. The first and cardinal step in the reform is made in considering this angle only, irrespective of the inclination of the prism faces or the refractive index of its material.

The reform is too evidently desirable to need argument in its behalf. It is accurate in principle and in fact, where our old system was gravely faulty. Against it can only be argued that the errors of our present numbering are of small practical importance, and that there are difficulties in introducing the new system. As to the sufficient approximation of the numeration now in vogue, Dr. Jackson has shown that at no point do the prisms in common use accurately give a deviation equal to one-half of the refracting angle, but that, beginning with a value of 0.54° actual deviation for the 1° prism (placed with one face perpendicular to the incident ray), the deviation increases more rapidly than the refracting angle until, at about 40° , they become equal—a 40° prism gives a little more than 40° of deviation. Beyond this, any small increase in the refracting angle gives a much greater deviation, until at 41.48° the "critical angle" is reached, and the deflected ray no longer emerges from the prism. Infinitesimal differences in the index or the refracting angle here greatly change the power of the prism. This condition is less quickly reached when the measurement is made in the position of minimum deviation; and it is only at 81° that deviation and refracting angle become

equal. Yet the fact holds good that the angle between the faces of the prism gives but a variable and indirect suggestion of its deviating strength—two 10° prisms do not equal a 20° , and it would take eight of them to equal a 40° prism. The deviating effect of the prism—the strength which it has to fulfil our uses—furnishes us with the rational basis for our enumeration.

TABLE SHOWING THE VALUE AND RELATIONS OF CENTRADS.

Centrads.	Arc or Angle.	Tangent (P. D.)	Ref. Angle (Index 1.54).
1.	$0^\circ.57295$ plus	1.	$1^\circ.00$
2	$1^\circ.14590$	2.0001	$2^\circ.12$
3.	$1^\circ.71885$	3.0013	$3^\circ.18$
4.	$2^\circ.29180$	4.0025	$4^\circ.23$
5.	$2^\circ.86475$	5.0045	$5^\circ.25$
6.	$3^\circ.43770$	6.0063	$6^\circ.32$

18	46.68	50.95				69.45	83.29	
20	52.36	57.75	64.35	75.0				

Our designation of prisms by the amount of deviation brings in the need of a new nomenclature. "Degrees" of prism have always in the past expressed the size of the refracting angle—"actual deviation" must now be expressed if we use degrees to indicate the *strength* instead of the *shape*, and the position of the prism must be specified. Accordingly, Dr. Jackson proposed that we measure in the position of minimum deviation, and add a small *d* to the number to indicate this. The system has advantages, and is upheld by Landolt as the best; yet the minimum deviation is not very convenient to measure pre-

cisely, such a mounting of our prisms would be inconvenient in our test-frames, and all computations are simpler if the entire refraction takes place at one surface. There would be inevitable confusion, also, between the old system and the new, since both use "degrees," yet mean very different things by that term.

The second step, suggested by Dr. Wm. S. Dennett, was very important, therefore, since it removed these difficulties. He proposed as a working unit a prism deflecting (through an angle subtended by an arc 0.01 the length of the radius) the ray of light falling perpendicular to one of its faces. This is the "centrad." The mathematicians, in seeking a better unit of arc and angle than the degree, have adopted the "radian"—an arc equal to the radius—and .01 of this is the "centiradian" which subtends the centrad. The new unit is distinct in name, in accord with advanced mathematics, and also—very important for its practical adoption—it is almost precisely the strength which we ought to obtain from a prism of 1° refracting angle. If made of light flint glass, instead of the usual crown glass, the equivalence would be exact for the smaller numbers, and the symbol Cr. instead of Pr. will be the only difference to mark the use of actual values in the place of the nominal.

A further step in commending the reformed system was made by Mr. Chas F. Prentice, in advocating a similar unit. His "prism-dioptré" deviates the ray of light through one one-hundredth of the radius as measured on the tangent instead of the arc, and for low values is identical with the centrad in strength. He has shown that, within narrow limits, it has relations at once simple and of great importance to the valuable "meter-angle" and to the decentering of lenses. In any given case one-half the inter-ocular distance in centimeters closely approximates "prism dioptrés" or centrads the value of one meter-angle. Thus for inter-ocular width of 50 mm. the meter-angle is equal to 2.50 P.D. or Cr. Yet the relation can be but an approximation, since one-half the inter-pupillary distance equals the sine of the meter-angle, not the angle itself; while the "prism-dioptré," being a tangent measure can represent neither precisely, and within practical limits the discrepancy is considerable. Thus for 7 cm. between the eyes, 5 M.a. equals 17.76 P.D. instead of 17.5. Ten M.a. would be 37.36 and 20 M.a. 98 P.D. instead of 35 and 70, respectively. Conversely 35 P.D. would represent 9.45 M.a., not 10. The centrad values are distinctly more close an approximation. For 7 cm. between the eyes 10 M.a. equals 35.74 Cr. instead of the even 35; and 20 M.a. equals 77.88 Cr. It must not be forgotten, however, that in this later case 35.74 and 77.88 are the accurate expressions in "radian" or "arcual" nomenclature of the values of

10 and 20 M.a. respectively—the discrepancy is here due to the inaccuracy of the convenient assumption that the meter-angle is *directly* expressed by the inter-ocular distance.

Mr. Prentice has also pointed out that in the decentering of lenses, the dioptric-strength of the lens multiplied into the centimeters of decentering gives the prismatic effect in "prism-dioptres." This is theoretically accurate, except for spherical aberration—in fact a 20 D. lens decentered 1 cm. (an extreme case, practically) gives 20 Cr. or 20.27 P.D. of deviation.

Such then are the main points in favor of the reformed numeration of prisms: the question is then as to which is the best of the systems proposed, or whether a further improvement can be made. Of the two simplest positions of the prism that in which all refraction takes place at one surface seems the more practical and simple, although the minimum deviation is easier to measure off-hand and permits the use of a wider series of prisms. An instrument of precision to measure the minimum deviation could be easily constructed and graduated to read in degrees or centiradians or tangent-centimeters. The prism-dioptre may be slightly easier to measure, since any wall laid off in even centimeters forms a ready prismometer. Yet the centrad is as easily and accurately measured by improvised or special apparatus, is in full accord with our received methods of noting deviation in terms of arc or angle, is more directly comparable and convertible, and finally, gives the closest approximation in the direct determination of the meter-angle and the prismatic effect of decentered lenses.

THE PRISM-DIOPTRY VS. THE CENTRAD.

Read in the Section of Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY SWAN M. BURNETT, M.D., PH.D.,
OF WASHINGTON, D. C.

I have had occasion to remark before, in respect to this question, that what we need in the nomenclature of prisms is scientific accuracy, readiness and simplicity of practical application with as little innovation in established custom as possible. The prism-dioptre, I believe, fulfills all these requirements. It takes as a standard prism one which causes a deflection of 1 cm. on a plane at one meter's distance, which is nearly what is now known as a one degree prism, and will thus entail no change in the present process of manufacture or in the plant of the manufacturers. It is scientific and accurate, every prism being precisely what its number indicates, and its power can be measured by any one having a centimeter rule and a meter measure. No

complicated apparatus is necessary, though for the finer determinations and for certain combinations of spherio-and cylindro-prisms the elegant instrument of Mr. Prentice is essential. It brings itself into harmony with the so-called meter angle and enables us to estimate the amount and power of convergence by a simple measurement of the inter-pupillary distance with an accuracy that is sufficient for all practical purposes, and, by the same or less amount of calculation than is necessary with the centrad or the present system, with perfect accuracy. It enables us to find the prismatic action of decentered spherical and cylindrical lenses with great exactness and with remarkable ease; one centimeter of decentration giving as many prism dioptries as the lens has dioptries of refraction. It enables us to measure the power of a prism combined with a spherical or a cylindrical lens more easily and readily than by any other method, and brings our lenses and prisms together upon the same basis of a uniform standard measurement distance of one meter.

In fine, the prism dioptre in accuracy, simplicity, ease of determination and width of application fulfills all requirements and leaves nothing to be desired as a method of numbering prisms. On the other hand the centrad, or centirad, as some prefer to call it,—is artificial, its principle is not recognized in optics, except by a few specialists in England, and it can serve no purpose that is not already served by the degree. It is based upon an angle corresponding to an arc equal to the radius, which is called a radian, and is equal to $0.57295^\circ +$. The .01 ($\frac{1}{100}$) of this is called a centrad and is proposed as a unit for prism measurement, and it was so proposed by Dr. Dennett, the originator of the scheme, because he says: if you use glass with an index of 1.57233 one centrad will equal 1° . (As a matter of fact this is not strictly so, as his table shows). This unit, please observe, is angular and nothing else was originally claimed for it, and, therefore, as a unit, the same objections are to be urged against it as against the minimum angle of deviation, with many additional on its own account.

Dr. Randall has said, in a discussion of this question, that we cannot get away from angles in the deflection of prisms. That is true in a certain sense, but the centrad departs farther from the angle as universally regarded in mathematics to-day than any other proposed method. Dr. Randall actually proposes, in his enthusiasm for the centrad, to do away with degrees altogether and abolish one of the fundamental units of optical science, one which forms an essential part of the great and enduring works of Helmholtz, Gauss and the numberless others who have made optics, technical and physiological, what it is.

Enthusiasm is good, but let us keep it within the bounds of sanity. Now the prism dioptre does not propose to abolish anything that is ex-

istant and in general use; it proposes no revolution. It keeps degrees, minutes, seconds, signs and tangents just where they were, and you can find the value of any number of prism dioptries in those reciprocals if you should happen to want them. Suppose, for instance, you wish to find the sign or tangent of three centrad, you have first to multiply .57295 + by 3, convert this result into degrees, minutes and seconds and then find their reciprocal sign or tangent in the table. This difference is much magnified when it comes to the application of the centrad to the meter angle, particularly if high degrees are used, for the difference between the centrad and the angle increases very much as the higher numbers are reached, not as much, however, it must be said, as between the prism dioptry and the angle, but the value in angles, of the prism dioptry, considered as a tangent, is much more easily found than that of the centrad. But, after all, the convergence need not necessarily be expressed in values of angles for any practical purpose. It can be expressed more simply and easily in prism dioptries. If absolute angles are wanted, as they never will be, since the error falls much within the limits of the personal equation, that accuracy is, as we have said, easily obtained. It is nonsense to speak of 20 meter angles, as is sometimes done, in illustration. Twenty M.a. means a convergence of five centimeters and that can never be used, and if it is applied to a deficiency of the convergence (negative), it is a condition that should not be corrected by prisms, but by operation.

In fact, all the anomalies known under the name of muscular insufficiencies can be most readily reckoned by means of the prism dioptry. In making examination for heterophonia, I employ the following simple methods. On the black wall of my ophthalmoscopic chamber I have ruled a number of squares in white lines 6 cm. apart. The flame of an argand burner, turned somewhat low, is brought to a point opposite the crossing of two of these lines at the center of the system of squares. In producing the diplopia I do not use a prism or a maddox rod, but take a 6D cylinder from the trial case, and place it before one eye of the patient, who is 6 meters from the light. By causing the patient to look near one of the curved edges of the lens we get the prismatic action of the cylinder in the form of a broad streak of light projected above or below the argand flame in examining for exophosia and esophosia. This causes no lateral deviation whatever, even when the lens is tilted. It should be turned, however, until the broad light streak is perfectly vertical and if there is any deviation to the right or left from the line on which the argand light rests, the distance is noted in the number of squares—each one of which corresponds 1 P.D. at the distance of 6 m. We are

then able to tell at a glance almost the character of the heterophonia and its amount expressed in prism-dioptrie.

In practice it is not the custom to use prisms stronger than 4 P.D. for a single eye, and I challenge Dr. Randall to detect the difference between the deflection of a 4 P.D. prism of one centimeter on the arc and on the plane. The difference cannot be measured by any means we have at our command. By all means let us be as accurate as we can, but let us not go outside the limits of reason and practicability; and while straining at this gnat of a purely theoretical, almost imaginary error, let us not swallow the camel of a new system which will necessitate the unlearning of a great deal that we have been taught, and which strikes at the foundation of our whole system of optics and leaves us practically none the better off.

After all is said, that which gives the centrad system any semblance of virtue and assures it any claim for acceptance has been taken bodily from the prism-dioptry. They say that one can measure the deflection on an arc at one meter, or at any chosen distance. But did any of the advocates say that before Mr. Prentice, with what seems like a flash of genius, put forth the simple idea of taking the linear deflection as a measure of the prism and adopting as a unit one having one centimeter deflection at a meter's distance? Take the deflection measurement away from the centrad and it has no advantage over the minimum angle and has many disadvantages which the angle has not.

It would be absurd to suppose that a man of the profound mathematical knowledge of Mr. Prentice had not thought of measuring this deflection on the arc. The fact is that was one of the things he wanted to get rid of in his effort at reducing the measurement to the simplest conditions possible. We have planes everywhere, but a different arc must be constructed for every distance. The purpose of the prism dioptry in its inception was to offer to the optician and to the busy practitioner a method of measuring the power of the prisms used in ophthalmology that should be simple, accurate, readily practiced, with as little change in our present methods as possible, and should bring it into harmony with the accepted notation of lenses, the meter angle and the decentering of lenses. In doing this I think it has been marvellously successful. On the other hand the proposed centrad system asks us to abandon one of the established units in optics, to adopt a system which is not used in our ordinary text books on optical science, and to unlearn much that we have already acquired through the labors of our great teachers in mathematical optics, and which cannot be made useful in the decentering of lenses or in measuring prisms combined with lenses and, only by twist-

ing, can be made applicable to measuring the meter angle. The centrad, as now advocated, is the prism-dioptry with the exception that the deflection of the centrad is measured on the arc, that of the prism-dioptry on a plane. The difference between these for practical purposes, is infinitesimal.

It is the law laid down in all treatises on optics from Gauss to the present time that we are to consider the arc, sign and tangent in all calculations where lenses are concerned as the same. If these masters in science who, by the adoption of this principle, have made technical optics possible, can do this we certainly cannot err in adopting it. In fact we cannot ignore it if we would not throw ourselves out of line with all previous investigation and study.

You have the two systems before you; one simple, scientific, easily executed and in keeping with all previous work, the other entirely new, revolutionary, requiring special apparatus for its use and with its only commendable feature taken from the prism-dioptry.

DISCUSSION.

DR. DUDLEY S. REYNOLDS said that he regarded it a very important matter to have some established basis for the measurement of prisms. It was desirable also to have as accurate values as possible, and this system of the centrad he considered comes nearest it. He acknowledged that there was a very small difference between the centrad and the refracting angle, but the former is more absolutely accurate. The difference, while almost infinitesimal, is at the same time real and it is the principle, scientifically considered, that caused him to advocate the centrad system. In adopting a new system it should be as accurate as possible. The centrad is not new, however, having been used in science many years. It is essential in circular measure that there be angles, nor can they be done away with.

As to centering lenses, he has demonstrated that the decentering by displacing is measured by the centrad and not by prism-dioptics.

DR. RANDALL said in closing, that he had laid most stress on the reform rather than the relative values of the prism dioptre and centrad. That he had already brought out in *The Med. News* of April 4th. His paper was a plea for accuracy, as rigid as possible, and he had demonstrated by the figures presented, that while the two units were generally identical, there were distinct differences even within the common practical limits and always in favor of the centrad. Our reform should introduce the minimum of change and the centrad changed only the unit, while the prism-dioptre changes both the unit and the method. As to the name, he feared that "prism-dioptres" would force "lens dioptres" upon us; and we were likely to lose rather than gain in clearness, when

each 1, 2, 3, 4, or 5 dioptres of accommodation, was stated to be accompanied by some 3, 6, 9, 12 or 15 P.D. of convergence.

The Congress of American Physicians and Surgeons.

Dr. Samuel S. Adams, of 1632 K. Street, Washington, D. C., has issued the following circular, dated August 8: I inclose herewith, for your information, a memorandum with regard to reduction of railroad fares for those attending the Second Congress of American Physicians and Surgeons. You will see from this that, to enable any member to obtain the reduction, there must be present at least one hundred persons holding special certificates. Will you, therefore, please notify me, without delay, as to whether you intend to avail yourself of this method of obtaining reduction in fare, and also whether you will be accompanied by any members of your family who will also desire to avail themselves of such reduction? Early in September the committee will inform you, by circular, as to whether one hundred persons or more have sent notice that they will avail themselves of this method of obtaining reduction, and will obtain special certificates for the purpose. In case there should not be one hundred persons who indicate their intention of doing this, only the ordinary reduction of rates on round-trip excursion tickets can be obtained by those coming to the Congress.

Reduction in Railroad Fares.—The Trunk Lines, the New York and Boston lines, the Southern Passenger Association and the Central Traffic Association, will transport persons from points on their lines to Washington and return, at the price of one and one-third the regular fare, on the following conditions: 1. There must be an attendance at the meeting of not less than one hundred persons holding special certificates. 2. The going ticket must be purchased within three days before the opening date of the meeting. 3. Each person availing himself of the concession must pay full first-class fare going to the meeting, and must obtain a certificate from the agent of whom the ticket is purchased. 4. Those holding such certificates, when countersigned by the proper officer at the Congress, can obtain return tickets at one-third the highest limited fare. *Certificates are not transferable, and the return tickets secured upon certificates are not transferable. If any of them are sold or transferred, they must be redeemed at the highest first-class rate by the person making such sale or transfer.* No refund of fare will be made on account of any person failing to obtain a certificate. Those who wish to avail themselves of this method of obtaining reduction in fares should present themselves at the office for certificates and tickets at least thirty minutes be-

fore departure of trains. It is absolutely necessary for each passenger, before starting, to obtain a certificate from the ticket agent of whom the going ticket is purchased, otherwise he can obtain no reduction in the return fare. There will be no stop-over privileges on the return tickets, which must always be by the same route as the going ticket. Members may obtain tickets on these conditions for their wives and members of their families, as well as themselves. Following is a list of the roads making these concessions:

Trunk Line Passenger Committee.—Reduction in Fare on Certificate Plan.—1. The reduction is to persons going to the meeting from Trunk Line territory—i. e., from Niagara Falls, Buffalo, and Salamanca, N. Y., Pittsburgh, Pa., Bellaire, O., Wheeling, Parkersburg, and Charleston, W. Va., and points east thereof, except in New England. *List of Roads making the Concession:* Addison & Pennsylvania, Allegheny Valley, Baltimore & Ohio (Parkersburg, Bellaire, and Wheeling, and east thereof), Baltimore and Potomac, Bennington & Rutland, Buffalo, Rochester, & Pittsburgh, Camden & Atlantic, Central of New Jersey (except locally between Philadelphia and New York), Central Vermont, Chesapeake & Ohio (east of Charleston, W. Va.), Cumberland Valley, Delaware & Hudson Canal Co., Delaware, Lackawanna, & Western, Elmira, Cortland, & Northern, Fall Brook Coal Co., Fitchburg, Grand Trunk, Lehigh Valley, New York Central & Hudson River, New York, Lake Erie & Western (east of Salamanca and Buffalo), New York, Ontario & Western, New York, Philadelphia, & Norfolk, Northern Central, Pennsylvania (except locally between Philadelphia and New York), Philadelphia & Erie, Philadelphia & Reading (except locally between Philadelphia and New York), Philadelphia, Wilmington, & Baltimore, Rome, Watertown, & Ogdensburg (except on Phoenix Line—stations between Syracuse and Oswego), Western New York & Pennsylvania, West Jersey, West Shore.

New York and Boston Lines Passenger Committee.—List of Lines making the Concession, and Points thereon from which it applies: Boston & Albany R. R., New York & New England R. R., New York, New Haven, & Hartford R. R., New York, Providence, & Boston R. R., Old Colony Railroad, Fall River Line, Norwich Line, Providence Line, Stonington Line.

Southern Passenger Association, composed of the following companies: Alabama Great Southern Railroad, Atlantic Coast Line, Atlantic & West Point Railroad, Brunswick & Western Railroad, Charleston and Savannah Railway, Central Railroad of Georgia, Cincinnati, New Orleans, & Texas Pacific Railway, East Tennessee, Virginia, & Georgia Railway, Georgia Railroad, Georgia

Central Traffic Association.—The territory of the Central Traffic Association is bounded on the east by Pittsburgh, Salamanca, Buffalo, and Toronto; on the north by the line of and including points on the Grand Trunk Railway, from Toronto to Port Huron, thence via Lake Huron and Michigan to the north line of Cook County, Illinois; on the west by the west line of Cook County and the Illinois and Mississippi Rivers to Cairo, including Burlington, Keokuk, Quincy, Hannibal, and St. Louis; and on the south by the Ohio River, but including points on either side of that river.

AMERICAN RHINOLOGICAL ASSOCIATION.—The ninth Annual Meeting of the Association will be held in Indianapolis, Ind., October 6, 7 and 8. The meeting promises to be an interesting one. Papers are promised, among others, as follows: "Nasal Stenosis from Inflammatory Action," by Dr. Christopher, St. Joseph, Mo. "The Abuse of the Galvano-Cautery in the Treatment of Diseases of the Ear, Nose and Throat," by Dr. Cheatham, Louisville, Ky; "Sarcoma of the Nasal and Pharyngo-Nasal Cavities," by Dr. Reinhold, St. Louis, Mo.; "The Voice Treatment of the Nose and Throat," by Dr. Hobbs, Atlanta, Ga.; "Surgery of the Nasal Fossæ," by Dr. North, Toledo, O.; "When Ante and when Post-Nasal Catarrh," by Dr. von Klein, Cleveland, O. Other papers are promised and some from applicants for fellowship in the Association.

President, Dr. R. S. Knodé, Omaha, Neb., Secretary, Dr. E. R. Lewis, Indianapolis, Ind. Inquiries may be addressed to either of the above officers.

ARISTOL IN IVY POISONING.—Dr. J. J. Levick reports a case in which severe poisoning from *rhus toxicodendron* was promptly much relieved by the free dusting of powdered aristol on the affected parts.

¹ Only for business originating at, or destined to, stations on the direct lines of these roads between Troy, N. Y., and Montreal, Can.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to
JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,
CHICAGO, ILLINOIS.

All members of the Association should send their Annual *Dues* to the *Treasurer*, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, AUGUST 29, 1891.

LINEAR CRANIOTOMY.

At the meeting of the Association last May, KEEN, of Philadelphia, read a paper on this subject, which appeared in a recent number of THE JOURNAL. DR. KEEN very properly objects to the term craniectomy, originally proposed by LANNELONGUE, and suggests instead linear craniotomy. The operation consists essentially of an incision through the cranium, usually parallel to the sagittal suture, but not necessarily so. KEEN reports eight cases, three of which he operated, two by LANNELONGUE, and one each by GERSTER and SACHS, WYETH, and MCCLINTOCK. GERSTER and SACHS's case and one of KEEN's died shortly after the operation. In WYETH's case the operation was quite different from that ordinarily done. He made two incisions through the skull, $\frac{3}{4}$ of an inch apart, and extending from a point just above the eyes to the occipital protuberance. Lateral incisions were then made at each end of these incisions, and also in the middle, and the four flaps of bone thus formed were forcibly torn apart, widening the original incisions by $\frac{3}{4}$ of an inch. The result in this case was satisfactory.

At the meeting, early in April, of the Fifth French Surgical Congress, LANNELONGUE reviewed this subject, basing his remarks on twenty-five operations.¹ LANNELONGUE finds an in-

dication for linear craniotomy in a number of other conditions besides microcephalism, with its premature closing of the sutures. In the so-called obstetrical compression, whether occurring during birth, or as the result of intra-uterine pressure during gestation, the operation appears to be indicated. Meningeal hæmorrhage in young subjects, circumscribed pachymeningitis, serous cysts, hyperostoses due to hereditary syphilis, certain forms of hydrocephalus, accompanied with thickening of the bones and premature closing of the sutures and fontanelles, all point to linear craniotomy as the proper mode of relief.

LANNELONGUE makes two operations, the "linear craniectomy," as he continues to term it, and "*craniectomie à lambeaux*." Besides the form already described, LANNELONGUE has made a transverse craniotomy in the frontal bone, and in the occipital bone. The "*craniectomie à lambeaux*," or flap craniotomy, consists in running the incisions so as to leave variously shaped bony flaps, after the manner of WYETH's operation, already referred to. This is the operation which LANNELONGUE is more and more frequently performing. Sometimes the flap includes a single bone, as the frontal or parietal, sometimes portions of two bones. The incisions are made in the shape of a T, a V, a U, a rectangle, or a horseshoe. As to the periosteum, the results are the same, whether it be resected or not. If the dura mater be cut, it should be sutured. The danger from hæmorrhage is unimportant; the meningeal artery and its branches are uncovered without danger. Great thickness of the cranium, hyperostosis, eburnation of the bone, present no difficulties.

In twenty-five operations he reports twenty-four operative successes, one death in 48 hours from acute septicæmia or loss of cephalo-rachidian fluid. Three times suppuration occurred, the longest duration being three weeks. No necrosis was seen. The youngest child was 8 months, and the oldest 12½ years. As to symptomatic results, he says that a very great number of the little patients have been improved either in intelligence or ability to walk.

In the discussion which followed, ANGER reported a case in a girl of 8 years, who was much improved. LARABRIC reported an operation by HEURTAUX on a child of 5 months, who died two months later without having shown any improve-

¹ Revue mensuelle des Maladies de l'Enfance, May, 1891.

ment. A most important case was reported by MANOURV, of Chartres, October 20, 1890; he made the linear operation on a four year old microcephalic girl who had never been able to walk or stand, who had double talipes equinus, who constantly moved the upper extremities, and who never pronounced a single syllable and was unable to chew her food. Immediately after the operation, the movements ceased, the talipes disappeared, the head was held up; and the face became more intelligent. The child chewed its food and was able to stand. This condition continued for two or three months, when gradually all the former troubles returned. Measurements of the head before and after the operation revealed no differences in size. The same operator reported a fatal case in a child of two years, death occurring by convulsions, twenty hours after the operation.

The latest American case reported seems to be that of DR. WM. H. MORRISON of Philadelphia, who successfully operated on a boy $2\frac{1}{2}$ years old, April 17, 1891.²

It is too early to derive conclusions from the operations reported, but it seems that the operation *per se* is not particularly dangerous and even if only occasional permanent good results are obtained, the operation should be made. No more pitiable objects exist than the unfortunate victims of microcephalism, with their idiocy, their paralyses, their general mental and physical incompetence, and they are certainly entitled to anything which may offer some prospect of relief. Education offers but little hope, and we have no other treatment at our disposal, so that the performance of craniotomy is not only justifiable, but a duty in these cases. With a view to the relief of certain cortical centers, it is possible that in individual cases the particular location of the incisions may be determined by the symptoms present.

THE USE OF MENTHOL IN PRURITUS.

Menthol has been found useful in the summer irritations of the skin, including those following the bites of mosquitoes, fleas and other insects. One part of menthol added to eight or ten parts of alcohol, or cologne water, will relieve not a few persons, but not all; at all events it is a pleasantly soothing and cooling application.

² Medical Record, July 18, 1891.

Some forms of head-ache, or brow-ache, are speedily relieved by the lotion containing one part in ten of menthol, the same being applied by rubbing, over the forehead and temples, with the hand or dampened muslin. Mixtures of menthol in glycerine and water have been commended for like purposes, but are not so suitable as the lotion above mentioned for use about the face, head and hands.

THE RELATION OF FUNCTIONAL DISORDERS OF THE HEART TO DISEASES OF THE ABDOMINAL VISCERA.

Under the above title DR. SEYMOUR TAYLOR presents a suggestive paper in the July number of *The Practitioner*. The matter is purely clinical, unaccompanied in any case reported by post-mortem examination, which is to be regretted, although to be commended as a report of careful clinical observation, after the manner of our forefathers, a habit altogether too much in disuse at present. The term "functional heart disorder" he uses in the sense as disturbed cardiac action in the absence of disease of the valves or muscular walls of the heart. He notes three cases of tachycardia, or heart hurry, and twelve of bradycardia, or slowness of pulse. The cases of tachycardia were characterized by suddenness of onset, being excited by such slight causes as a sudden noise, or mental emotion. The attacks would terminate with equal suddenness. Dangerous syncope was frequently present and two of the cases died during an attack.

In one of the cases, the pulse rate reached 200, and in another 270 per minute. The only discoverable structural lesions were in one case, a movable kidney, in another a large uterine tumor, and retroversion, and in the third enlarged prostate with chronic cystitis.

ORD has distinctly shown that a reflex destructive or dystrophic change occurs in the skin and joints secondary to uterine, or prostatic or urethral disease. Assuming a causal reflex nervous influence, TAYLOR thinks that the original irritation from the abdominal or pelvic disease may act higher in the cord and be reflected to the cord causing a motor disturbance.

Of the twelve cases of slow or intermittent heart action, three occurred after enteric fever, five in cases of chronic bladder and prostatic trouble, three had chronic bowel trouble, and in

one, pregnancy was the abdominal trouble. A diminished pulse rate and subnormal temperature are not uncommon after typhoid fever.

The cases cited are by no means proof of a causal relation between abdominal lesion and functional heart trouble, nor is it clear that the effects of nutritional disturbances, or of cardiac obesity have been eliminated, yet still they make it desirable that possible connections of this type should be more closely noted.

ON THE VALIDITY OF STATISTICAL PROOF IN MEDICINE.

The following axiomatic statement occurs at the head of a book review in a recent number of the *Lancet*: "The true and sufficient reply to the oft-quoted allegation that one can prove anything by statistics is that without them one can prove nothing." This is putting the case in strong language, to say the least, and yet there is so much in it of rebuke to those who would belittle the authority of statistical statement that we would be glad if we could give emphasis to the quoted paragraph, with the name of its acute composer. When we reflect how much in the past history of scientific medicine has been due to the master in statistics, and how much in future must depend upon him, we stand ready to honor the philosopher who could indite so clear and righteous a decree.

THE MEDICAL BUREAU OF THE COLUMBIAN EXPOSITION.

This very necessary adjunct to the great Fair was organized June 1, 1891. Staff: Jno. E. Owens, M.D., Medical Director; W. H. Allport, N. R. Yeager, S. C. Plummer, Assistant Surgeons.

The Bureau took charge of medical, surgical, and sanitary inspection work on the grounds July 1, 1891, and is now in active operation.

A temporary dispensary and emergency hospital has been constructed, where medical and surgical attendance and medicines are furnished to employes during the day free of charge.

The Bureau is amply equipped with instruments, medicines, operating room furniture, stretchers, cots, and an orderly. The City Police Department has furnished a patrol wagon for ambulance service to be used until a perma-

nent ambulance has been constructed, and the Exposition company provides horses, harness and driver.

The present Bureau operating during the construction period will be the nucleus of the medical service of the World's Fair. It is the intention of the Medical Director to make the records of the Bureau as complete as possible from a statistical and historical standpoint, and to furnish at the close of the service a report which will be valuable in the organizations of the Medical Bureaus of future Expositions.

Present number of persons living or working on the grounds is 2,000, increasing weekly. Several accidents have already occurred, and the Bureau has had ample opportunity to demonstrate its right to existence.

NECROLOGY.

Richard Lea McDonell, M.D.

Dr. Richard Lea McDonell, of Montreal, died July 31, aged thirty-eight years. He was professor of clinical medicine at McGill University and physician to the Montreal General Hospital. He was the son of an accomplished physician from whom he inherited fine intellectual powers and an unquenchable fondness for medicine. He was one of the best and most popular among the junior professors in the University, being notable for his punctuality and careful preparation as well as for his fine literary capacity and a ready diction. He was active in the medical societies and with his pen in both American and English periodicals. About two years ago he was taken with a severe pulmonary hæmorrhage, which impelled him to give up his professional work for a year, and to travel in Europe. He spent most of this time among the Alps, and his health was so far improved that there appeared to be an arrest of the disease. He resumed work, and during the last session of the college was in vigorous health, and so continued until a few weeks since. But his pulmonary troubles returned and advanced rapidly during July, carrying him off in the prime of life, a sacrifice to tubercular phthisis.

John Joseph Cochran, M.D.

Surgeon John Joseph Cochran, U. S. A., died August 6, at the St. Luke's Hospital, New York City. He was a native of Cambridge, Mass., from which State he was appointed to the Army about ten years ago. He was an alumnus of the College of Physicians and Surgeons, New York, of the class of 1876, and for a short time served as surgeon on one of the Cunard liners, directly after his graduation. He attained to the grade of captain in 1885. His fatal illness was typhoid fever.

BOOK REVIEWS.

A TEXT-BOOK OF THE DISEASES OF THE EAR. By DR. JOSEF GRUBER, Professor of Otology in the Imperial Royal University of Vienna, etc. Translated from the second German Edition, by special permission of the Author, and edited by Edward Law, M.D., C.M., Edin., M.R.C.S., Eng., Surgeon to the London Throat Hospital for Diseases of the Throat, Nose and Ear, and by Coleman Jewell, M.B., London, M.R.C.S., Eng., late Physician to the London Throat Hospital. With 150 Illustrations and Seventy Colored Figures on two Lithographic Plates. New York: D. Appleton & Co., 1, 3 and 5 Bond St. 1890. Compliments A. C. McClurg & Co., 117-121 Wabash Ave., Chicago. Price \$5.00.

Those who are specially interested in the study of diseases of the ear and their treatment, will recognize the thoroughly helpful work which has been accomplished by Professor Gruber. Himself a self-taught man, he has not forgotten the successive steps of progress by which he has attained his present eminence as a practitioner and teacher, and from his personal experience, he is the better able to conduct his students along the ways now so familiar to him. His English editor, Professor Law, his former pupil, assisted at the first by the late Dr. Coleman Jewell, appreciating the value of the work, has given to the English-speaking people a fine translation of the same, and the publishing house of D. Appleton & Co., New York, have placed upon the American market an exceptionally fine edition of this excellent work.

Recognizing the absolute importance of a critical knowledge of the anatomical structure of the parts which, directly or indirectly, may be involved in diseases of the ear, the author has performed this part of his work in a most creditable manner. In the present edition, it has been submitted to the able supervision of Dr. Howden, Lecturer on Anatomy in the University of Durham College of Medicine, and the thoroughness with which his work is done leaves little more to be desired. So far as we can judge, the illustrations are original, and in each instance they are exceptionally fine. When we come to consider the functions of the several parts of the aural organism, we are confident that less progress has been made than in the study of almost any other organ or structure of the body. For instance, who of all our investigators, is fully satisfied in his own mind as to the physiology of the labyrinth? Then again, such are the minuteness and delicacy of the structures that, in the progress of disease, rarely is one alone involved, often rendering it exceedingly difficult to determine which

is responsible for a given set of symptoms manifested during life.

One by one the component structures are carefully considered, their physiological uses, according to the author's view, are stated, and their diseases and treatment clearly set forth. Ample instruction is given for the proper examination of patients. The instruments needed in the treatment of aural affections are well described and illustrated. With such a work at hand, there is no excuse for that amount of uncertainty, and of positive ignorance, which so largely prevails among the masses of the profession, with reference to the diseases of the aural organism, and the most approved methods of treatment.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

As a considerable portion of the last letter was devoted to the ambulance service of the city, in connection with the report of the grand jury's committee, a few particulars in regard to the life of the ambulance surgeon in our hospitals may perhaps be of interest. This responsible official usually sleeps on a cot immediately above which are placed two large gongs. One is the regular fire gong, and when an ambulance call is sent through the fire-box this rings 20, and then the number of the district. The other gong connects with the telephone, which keeps on ringing till he awakes and pulls a string for it to stop. As soon as he hears the call he touches a button which gives the signal at the stable, where the horses are trained to spring to their places in the same way that the fire department animals answer an alarm. The ambulance surgeon is allowed from three to five minutes in which to dress and get to his position on the ambulance.

When two districts lie close together it is a point of honor to see which ambulance will be first on the ground; consequently there is considerable rivalry as to which brings in the case. It is related that on one occasion when a case occurred about the middle of the new Washington bridge on the Harlem, the ambulances from two different hospitals simultaneously arrived at opposite ends of the bridge. There was then a hot race to get to the patient first, and as both of the ambulances dashed up exactly at the same minute, there was considerable wrangling between the rival surgeons and drivers as to which hospital was entitled to him.

The ambulance surgeons sometimes have some very exciting experiences, as well as sometimes very amusing ones, and when a young man first goes on to this service he is likely to find his position a very trying one. All drunk and insane cases are, as a rule, required to be taken to Bellevue, and if the patient has to be carried from a long distance, as Harlem, for instance, the ambulance surgeon's lot is not always a happy one during the drive. One of them relates one of his experiences as follows: "One Sunday when I was coming down through the

Park and Fifth avenue with a case of delirium tremens I didn't know but I would have to be taken inside with nervous prostration myself before we got through. That miserable wretch would wait till we got right in the midst of a lot of swell turnouts, with ladies and children inside and solemn coachmen and footmen on the outside, and then he would let forth the most fiendish yells and shrieks, and struggle until it seemed that he would break every strap which held him down. Sometimes the horses near by would shy, the ladies would look frightened half to death, and everybody would gaze at me in a manner that was extremely depressing to a quiet, retiring sort of a man. On arriving at the hospital the patient insisted that we had kept a big black dog in with him all the way, and that the beast had bitten him several times." Not infrequently impostors and maligners, who want to have a few days comfortable lodging and board free, contrive to get taken to the hospitals, especially after dark; but when, as is often the case, the actual cautery is prescribed for the treatment of the supposed injury or disease, it takes an astonishingly short space of time to get rid of this class of patients. The sight of the iron, even before it is heated, is generally sufficient to produce an instantaneous cure.

Among the Sisters of the Poor of St. Francis who have charge of the nursing in St. Francis' Hospital, which is situated on the east side of town, in the midst of a dense German population, is one, Sister Emerana, who, by her life of devoted zeal for the relief of suffering and sorrow, has won for herself among the hospital people the title of "Captain of the Wretched." She was born in Germany, and at an early age assumed the vows of the religious life. When the Franco Prussian war broke out, she left the peaceful convent where she resided for the battle-field, and did heroic service as a nurse in the camp hospitals attached to the German army. It sometimes happened that the wounded were brought in in such numbers that it was impossible to give them all immediate surgical care, and the brave young nurse had to do what she could to supply a surgeon's place. She thus gained an experience in practical surgery and the dressing of wounds that has since proved of the greatest value. At the end of the war she labored for a time in the various hospitals established by her religious order in Germany, and some years ago came to America. At St. Francis' Hospital she is invaluable as a nurse and as an assistant at operations, and in the outdoor department, where every morning a number of patients crowd in from the street to have their wounds dressed, a large part of the work is done by her. At the same time she humbly takes her share in the daily scrubbing of the hospital wards, and although possessed of great natural capacity to govern others, she is always rigidly obedient to the rules of her order. In any sphere of life Sister Emerana would have been a remarkable woman. In that which she has chosen she furnishes a beautiful example of heroic self-sacrifice, leading her little company courageously forward in the grim battle with suffering and death; lifting up the fallen, cheering the faint-hearted, and soothing the last moments of the dying.

The newspapers report the case of a patient in St.

Joseph's Hospital, in the neighboring town of Paterson, N. J., who practically fasted for sixty days, although he did take a cup of tea or a glass of water from time to time. Some two months and a half ago the man was admitted, suffering from an injury to the spine which it was thought would prove fatal. He was unable to retain food, and, losing all taste for it, he determined to do without eating for a time. He was carefully watched, and although he became excessively emaciated, he remained cheerful, and stated that he felt much better than when he attempted to eat. At the expiration of sixty days he said that he felt like eating something, and "thought he would like a piece of home-made pie." The account does not mention whether his physicians gave their consent to the patient having his pie, but at all events, it was given him, and it is stated that from that time he began to improve rapidly, and now expects soon to leave the hospital quite well.

In the case of a laborer who was overcome by the heat one day recently during the hot weather, and who was taken to the Presbyterian Hospital, the patient's temperature is said to have reached the extreme point of 111°. The man recovered.

One would hardly select a crowded excursion barge on the Hudson River as a place of accouchement, yet the other Sunday an Irish woman gave birth to a child, without medical assistance, on a trip of this kind, in only such seclusion as the captain's cabin afforded. There were altogether five thousand people on board the two barges used for the excursion, dancing and otherwise enjoying themselves, and the rapidity with which the news, "it is a boy," spread among them, is said to have been something extraordinary.

P. B. P.

MISCELLANY.

MESSRS. J. B. LIPPINCOTT COMPANY announce that they will publish, about September 1st, the eighth edition of Wood's Therapeutics; its Principles and Practice; rearranged, rewritten, and enlarged. Scarcely three years have elapsed since the appearance of the seventh edition, yet the preparation of the present volume has necessitated a careful study by its author of more than seven hundred memoirs. In the present edition no revolutionary changes have been made comparable to those of the seventh revision, but great care has been exercised to see that every portion of the work has been thoroughly revised, and a number of the articles have been completely rewritten, while some new drugs have been noticed. Among those portions of the book which are practically new may be mentioned, as important, the whole subject of anæsthetics, the articles upon cocaine, strophanthus, caffeine, antipyrin, antefehrin, phenacetin, hydrastine, paraldehyd, lead-poisoning, etc. Among the absolutely new articles may be mentioned sulphonal, chloralamid, aristol, and others.

RESIGNATION OF A QUACK EXTERMINATOR.—Dr. John H. Rauch, the efficient Secretary of the Illinois State Board of Health since its organization in 1878, and prior to that of the Chicago Board of Health, has resigned. He was the terror of quacks and ignorant pretenders, for whom he made it so hot in Illinois that they had to seek hospitality in neighboring States. His

chosen motto was "down with quackery!" or words to that effect, though as an official he was a man of action rather than words. His warfare against the parasites was not mere smoke—there was fire behind it, a smoldering magazine, as the miscreants soon found out to their sorrow. He not only drove them out of Illinois, but his method of dealing with them was contagious, and other States caught the idea and enacted laws for the suppression of quackery patterned after that of Illinois. He was also an indefatigable worker in the department of sanitary science and inaugurated many reforms in the administration of public health affairs in Illinois. It has been chiefly through his work that the standard of medical education throughout the country has been elevated to its present position, for the requirements of the Illinois State Board of Health have been largely instrumental in developing a more thorough course of instruction upon the part of medical colleges. In his resignation the Board sustains an irreparable loss.

CAFFEINE.—Dr. Gempt urges the use of caffeine in cases of threatened collapse in various asthenic diseases, but especially in acute pneumonia, and cites several cases in which it was successfully used in conjunction with stimulants. He believes the drug indicated in the course of acute pneumonia when there is evidence of cardiac failure, such as rapid, irregular pulse with lowered tension. Should the pneumonia be of asthenic type, it should be used from the onset, and the earlier in the course of the disease it is used after asthenia develops the better. In cases of this sort, caffeine, in doses of .35 gram four to five times daily, raises the arterial tension, diminishes the rate of the respiration and pulse and lowers the temperature. Its action is prompt, but in urgent cases it had better be used hypodermically. It is advisable to continue it for a brief period after the febrile defervescence.—*Boston Med. and Surg. Journal.*

AN IMPROVED METHOD OF GRAFTING ULCERS.—Having had an exceptionally large number of chronic ulcers of the leg, which incapacitated the patients from work, and finally brought them into the infirmary, I tried the ordinary methods of grafting, but being disgusted with the very large number of total failures I experienced, I undertook various experiments, and at last adopted the following plan, which I distinctly disclaim as my own, but which consists in adopting and combining the ideas of several people. The success I obtained with this method was so marked that I think a large number of practitioners at home and abroad (in India especially, where I found all ulcers very intractable under ordinary treatment) will welcome it. Even when the ulcer is deep, with hard thickened edges and extending all round the limb, the method applies. This is to cleanse the surface well for two or three days with boracic fomentations, and then (contrary to what I was taught) slightly abrade the granulations, just sufficient to cause oozing, and apply the graft directly to the abraded surface, where it is held in position by a small pile made of half-inch squares of green protective, four or five squares being placed one on the top of the other. A graft is thus applied to every square inch of surface. And now comes the most important thing of all, and which is an idea I received from a friend. This is to encircle the limb with a fold of carbolic gauze, which extends two or three inches above and below the ulcer, where it is attached to the sound skin by collodion. The ulcer is then thoroughly dredged with boracic powder through the gauze, and the whole is wrapped in a layer of wet boracic lint, which is kept thoroughly moist. As a rule, the dressing is not disturbed for three days, when the lint is removed, and the limb well irrigated with boracic lotion, the grafts remaining perfectly secure under their heaps of protective, which is again kept in position by the gauze.

The limb is then redusted with boracic powder, and

done up in the wet lint, which is now changed daily. At the end of ten days the gauze and protective are removed, and each graft will be found as large as a sixpence, while those near the edges will have exercised a spermatic influence, and caused a rapid ingrowing of epithelium. Since adopting the above plan, I may say I never lost a single graft, though employed on most unfavorable surfaces—a very different result to the old way of covering the grafts with a large piece of protective which retained some exudations under it, and thus bathed the tender graft in a poisonous medium, with a result that 80 per cent. of them never "took."—Gill, *The Lancet*.

SPINAL INJURIES.—If your patient is really suffering from a spinal lesion, you may expect to find one or more of the following *objective* symptoms to exist, to-wit:

1. Emaciation. Generally most noticeable in groups of muscles deprived of normal nerve stimuli.
2. Fibrillary twitchings and tremors of individual muscular bundles.
3. Flushings, generally confined to face or upper portion of body.
4. Heart and pulse conditions, if abnormal and not existing before injury, may reasonably be referred to the injury.
5. Ephidrosis, indicating a depressed nervous condition.
6. Cold extremities, a symptom not possible to feign.
7. Cyanosis.
8. Pupillary dilatation, indicating nervous irritation.
9. Condition of reflexes.

In conducting the examination in medico-legal cases avoid leading questions.

It is my custom to let patients describe their symptoms or tell their story without the least suggestion from me. It is your duty to ascertain if your patient has read any work upon spinal injury since the accident, and before arriving at a definite diagnosis consider the patient's former character, especially as to veracity.

I believe it well to make repeated examinations, as different examinations may reveal widely different results.

In conclusion, you will find it impossible to arrive at your diagnosis from any one or any two symptoms, but rather from the aggregate phenomena that go to make up the clinical picture.—*Millard, N. W. Lancet.*

STERILIZATION OF CATGUT.—C. Brunner (Zurich) recommends the following method for the sterilization of catgut:

Place for one or two days in ether, then place in xylol, using a preserve glass, and heat in a sterilizing apparatus for three hours, wash with alcohol to remove the xylol, and keep in a solution of 1 part sublimate, 900 parts absolute alcohol, and 100 parts glycerine. After three days the catgut is ready for use. Before using pass the catgut through a sublimate solution (aqueous).—*Beitrag zur Klin. Chirurgie.*

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from August 15, 1891, to August 21, 1891.

Lieut.-Col. Joseph C. Baily, Asst. Medical Purveyor, granted one month's ordinary leave, in extension of sick leave.
Asst. Surgeon Charles M. Gandy, U. S. A., will, upon the final adjournment of the Army Medical Board, resume his leave of absence.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending August 22, 1891.

P. A. Surgeon W. R. DuBose, ordered to duty at Naval Academy, Annapolis.

Surgeon G. E. H. Harmon, detached from Naval Academy, Annapolis, and wait orders.

Surgeon Howard Wells, ordered for temporary duty at Naval Station, New London.

Medical Inspector A. A. Hochling, Surgeon J. B. Parker, and P. A. Surgeon O. D. Norton, ordered to Naval Academy, Annapolis, September 3, to examine physically candidates for admission to the Naval Academy.

ORIGINAL ARTICLES.

FURTHER CONTRIBUTIONS TO KERATOMETRY.

Read in the Section of Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY SWAN M. BURNETT, M.D., PH.D.,
OF WASHINGTON, D. C.

Professor of Ophthalmology and Otology at the Georgetown University, Ophthalmic and Aural Surgeon at the Garfield Hospital, Providence Hospital, and the Children's Hospital, Director of the Eye and Ear Clinic at the Central Dispensary and Emergency Hospital.

It is now nearly seven years since I began to use the ophthalmometer of Javal and Schiotz daily in my practice, and six years since I published my first results from its use.¹

I appreciated the great practical value of the instrument from the beginning, and have persistently attempted to keep its importance as an instrument of diagnosis in astigmatism before the profession. For a time the apathy and indifference to its value were as intense here as they still seem to be in England and Germany, but recently there have been evidences of a greater interest in the instrument, so that, whereas six years ago, so far as I am aware, there were only three in use in this country, there is now, I understand, difficulty in getting orders for it filled.

In my Treatise on Astigmatism,² I made the statement that I regarded it as the most important instrument of positive diagnosis given to us since the invention of the ophthalmoscope, and I have as yet no cause to retract or modify that opinion. It must be borne in mind, how-

ever, as has been said before, that the principal use of the instrument is in the determination of astigmatism. Of the general refractive condition of the eye it gives us no idea. General ametropia, with only the rarest exceptions, is due to variations in the length of the eye-ball; on the other hand, the use of this instrument has taught us how constantly astigmatism has its seat in the cornea. Previous to the introduction of this instrument, this was more or less of an assumption. In one of my statistical papers,³ I have shown how rare it is to find astigmatism any other than according to rule, that is astigmatism with the greatest curvature in, or approaching the vertical meridian. The examination of several thousand eyes since that time has confirmed that statement fully. It is also a fact that it is very seldom we find a cornea without a measurable degree of astigmatism. Normal corneal astigmatism I would place at 0.25 or 0.5 D., and according to the rule. This is true of eyes in which every test has shown the existence of emmetropia, this no glass, spherical or cylindrical, has improved vision for our test letters. Now a half dioptre of total astigmatism, or even less, is very demonstrable subjectively, and is often the cause of asthenopia, so that it would seem that this corneal astigmatism must be corrected by an astigmatism of the lens of an equal degree, which is, moreover, contrary to the rule.

This lenticular astigmatism may be due to an unequal contraction of the ciliary muscles, causing an astigmatic curvature of the lens surfaces, or to a tilted position of the lens respecting the visual axis.

The latter, in my opinion, is much commoner than is generally allowed, particularly as a corrective of the normal astigmatism of the cornea. I am fully aware that we are not, as yet, in possession of sufficient data for final generalizations, but the indications point to something like this: Normal astigmatism of the cornea, according to the rule, probably due to lid pressure; corrective astigmatism of the lens, contrary to the rule, probably due to the rotation of the lens on its vertical axis, cause undetermined.

My observation leads me to believe that this

³ Refraction of 576 Healthy Human Corneæ, Trans. Am. Oph. Soc., 1888.

lenticular astigmatism against the rule is nearly always present, for when I find the ophthalmometric readings show either no corneal astigmatism or a slight astigmatism against the rule, there is tolerably certain to be an astigmatism demonstrable subjectively against the rule. So constantly have I found this to be the case that I have formulated the following law to which there are, I think, only occasional exceptions: For the total subjective astigmatism, subtract 0.5 D. from the corneal astigmatism when it is according to the rule, and add 0.5 D. if the corneal astigmatism is against the rule.*

In a healthy eye I think this astigmatism, due to the turning of the lens on its vertical axis, rarely exceeds 0.5 D. When the lenticular astigmatism is greater than that I suspect an implication of the ciliary muscle and resort at once to a mydriatic.

I do not believe, as some appear to do, that the ophthalmometer enables us to dispense altogether with paralysis of accommodation, but it does, I think, make the necessity for its use less frequent, and the indications more direct and certain. For example: the ophthalmometric readings show 2 D. of astigmatism according to the rule, whereas the subjective test shows none at all or probably 0.75. I then suspect a partial accommodation which neutralizes the 1.25 D. of corneal astigmatism remaining, and usually a mydriatic brings it to light.

The form of the cornea of the two eyes is usually approximately the same, that is to say, if there is a corneal astigmatism it is nearly always of the same variety. To this, however, there may be exceptions, one of which I have seen, and is so unusual that I will here record it:

B. F., a girl of 13, had in the left eye a corneal astigmatism of 2.5 D., contrary to the rule, the right had a corneal astigmatism of the same degree, but according to the rule. Under a mydriatic perfect vision was obtained in the left with -2.5 axis 90° , and in the right with -0.75 \bigcirc -2.5 axis 180° , showing that the astigmatism in both eyes was wholly corneal, though of opposite kinds. The emmetropic meridian was the same in each, viz., 41 D.

Another fact which has been brought out by the use of the ophthalmometer is that the form of the cornea is often permanently changed by injury or disease. In my paper on "Astigmatism Resulting from Cataract Extraction,"⁴ I have shown that there is invariably an astigmatism contrary to the rule during the first weeks of healing of the wound. This astigmatism is sometimes enormous, amounting, as I have seen it, to as much as 8 D. Naturally, the visual acuteness of such an eye would be very much

reduced during the period of existence of this astigmatism, and which may extend to two or even three months. It is rare, however, to find an astigmatism above 3 D. persist after the perfect healing of a normal extraction.

I have not been able to demonstrate the existence of an astigmatism of the cornea following the operation for strabismus.

Astigmatism from trauma is seldom seen when the cornea is not involved. It is commonly found after an iridectomy, and may follow other injuries to the eyeball affecting the sclero-corneal junction. An interesting instance of traumatic corneal astigmatism is the following:

A. F., aged 29 years, received a blow on the left side of the head and eye from the bursting of a bottle. When I saw him, two or three days after the accident, there was some blood in the anterior chamber and an apparently superficial keratitis, but there was no solution of continuity anywhere in the ball. The blood was rapidly absorbed, and no evidence of internal injury was found. Some weeks later the keratitis returned, but yielded readily to treatment and the patient passed from observation. Three years later he returned for the purpose of having the eye re-examined, supposing that the diminished vision was due to the injury, and moreover was permanent. An examination with the ophthalmometer showed an astigmatism of 0.5 D., according to the rule, and vision equal to $\frac{5}{8}$ in the right; in the left the ophthalmometric measurement revealed an astigmatism of 1.5 D. at 135° and with $+1$ \bigcirc -2 135° , vision = $\frac{5}{8}$. As the man stated that he was sure that his vision in the left, before the injury, had been equal to that of the right, we must conclude that the astigmatism was due to change in the form of the cornea produced by the injury, particularly as the meridian at 45° was 1.5 D. less than the weakest meridian in the right.

The following case shows in a most pronounced manner the changes that can come to the form of the cornea from long continued inflammation:

Mr. C. P., aged 32, was taken six years ago with acute trachoma accompanied with intense keratitis in both eyes. The left was virtually destroyed, and was finally removed on account of continual pain. When I saw him first in 1888, soon after this enucleation, the right cornea was in a condition of intense pannus, and vision was reduced to little more than perception of light. I treated the granulated lids with the solid copper stick, and in course of time improvement began, which continued until the cornea became almost perfectly clear. Vision was still, however, very low, fingers being counted only at two meters. In December, 1890, I made a keratometric examination and found the following condition: 100° 51 D., 10° X 2.5,—that is to say in the meridian with axis at 100° there was

⁴ I learn that Dr. Bull, of Paris, has formulated a similar law, using, however, 0.75 instead of 0.5 D. This I consider too high for the majority of eyes examined by me.

⁵ American Journal of Ophthalmology, December, 1889.

an access of 8 or 9 D. over the normal refraction (the normal being from 41 to 43 D.), with a still further increase of 2.5 D. in the opposing meridian. With $-9 \text{ } \ominus -2.5 \text{ } 10^\circ$ vision advanced to $\frac{5}{8}$. The form of the cornea examined by Placido's disk showed no irregular astigmatism. The patient was most positive in his statement that previous to the inflammation his distant vision was good, and that while living on the plains he could distinguish small objects at a distance better than most of his companions. Assuming then, as is warranted, that the eye was emmetropic to begin with, we have here a corneal myopia of 9 D., and an astigmatism of 2.5 D. according to the rule, which we can probably refer to pressure exercised on the cornea when it was in an inflamed and softened condition. The kind of astigmatism would seem to carry out our idea that astigmatism according to the rule is caused by lid pressure.

That the changes from inflammation in the cornea, however, are not always those causing an increase of curvature is shown by the following case:

H. M., aged 16, suffers from the interstitial keratitis of inherited syphilis. She was under observation for a number of years, and was almost totally blind from the corneal combined with uveal inflammation. The cornea cleared up to a degree after a time, and in the left there was some useful vision remaining; the right was practically useless. Measurements of the left cornea gave the following: $15^\circ 35 \text{ D. } 120^\circ \times 2\frac{1}{4} \text{ D.}$ The form of the cornea was only moderately irregular, but there was a lessening of curvature amounting to at least 6 D. in its general refracting power, with a further diminution of 2.25 D. in one of its meridians. A $+2.5 \text{ axis } 90^\circ$ increased vision from counting fingers at 3 meters to $\frac{5}{10}$. The $+6 \text{ D.}$ did not give an additional improvement.

A few words now in regard to the practical use of the instrument: It is true that it is not an apparatus that requires much time or practice to learn to manipulate properly, and yet certain conditions for its most successful operation are essential. In this country I do not think artificial illumination is at all necessary when a window can be used, which looks out to the open sky; but the relative positions of the instrument and the patient should be such that the patient's body does not form any obstruction to the light falling on the white bands in any position of the arc. This particular position, however, can be readily found by experimenting. It may not be without interest or value to those beginning the use of the instrument to know of the method I have found most satisfactory in recording ophthalmometric measurements. It is the shortest and simplest possible. I first find the meridian of least refraction as shown by the touching of

the two hands at their bases, I note the direction of this meridian, and then turn the arc until the bases of the bands are even again when the crossing of the one over the other is greatest. This amount of crossing I read on the corneal reflex, and note the meridian in which it occurs. The position of the right movable band on the arc gives the refraction of the weakest meridian in dioptries. This gives us all the necessary data, and I record it as follows, for example: $L. 45^\circ 23, 135^\circ \times 2$; this means that the meridian at 45° has a refraction of 43 D. (since 20 D. has to be added from the position of the white band on the left-hand-side of the arc to the position of the band on the right-hand-side, in order to get the total refraction of that meridian in dioptries). This, as you see, gives us, at a glance, the refraction in the weakest meridian, the direction of that meridian and the difference expressed in dioptries, between that and the refraction in the strongest meridian shown in the number of steps crossed, which is, of course, at right angles to it.

THE FULL CORRECTION OF AMETROPIA.

Read in the Section of Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY EDWARD JACKSON, A.M., M.D.,

PROFESSOR OF DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC, AND SURGEON TO WILLS' EYE HOSPITAL.

There is fairly general agreement that theoretically the emmetropic eye is the ideal eye; that it approaches its work under the most favorable conditions, that its possessor is to be congratulated, and that when an ametropic eye suffers from strain, one of the most important things that can be done for it—no matter what the kind of ametropia, no matter what its grade—is to give it the optical aids that will make the conditions under which it works more nearly approach those of the emmetropic eye. But in practice, I am aware that very many of you will not agree to follow the logical train to its legitimate sequence, that the best optical aid that you can furnish the ametropic eye is that which will most exactly conform its conditions of labor to those of the emmetropic eye; that is, the full correction of its ametropia.

The position that if the emmetropic eye works under the best possible conditions, the conditions that most nearly approach these are the best that can be secured for the ametropic eye, is so strong, that the burden of proof must be held to lie entirely on those who contest it. Let us examine some of the things that are urged against the full correction of ametropia.

It must be admitted, in the first place, that a lenses cause, when first used, certain disturbances in the relations of the visual acts. spherical lens disturbs the relations betw

commodation and convergence, and differences between the correcting lenses of the two eyes necessitate a revision of the act of binocular fusion. On these accounts, for every pair of glasses put on there must be a longer or shorter period of adaptation. Of this period I can only say that other things, *including the strength of the glasses*, being equal, I am convinced that this period is on the whole apt to be less prolonged and less annoying when the correction for ametropia is a complete one, than when it is partial.

Taking up the objections to a full correction, in the various forms of ametropia, of astigmatism I shall say nothing, for the objections to its full correction are not generally allowed to influence practice, and have to do solely with the period of adaptation.

HYPEROPIA.

In hyperopia it is urged that patients will not or cannot see clearly at a distance if given the correction for total hyperopia. Probably the majority of ophthalmic surgeons believe this to be the case, and each could adduce cases innumerable to support his opinion. But let us see if there be not some more rational explanation of these cases, than the one of supposing that the hyperopic eye is subject to a species of inveterate normal "spasm" of the ciliary muscle, from which other eyes are quite exempt. I have never seen a case of such spasm that did not yield, allowing perfect distant vision with the correction for total H., within two months of the constant wearing of the lenses. I have seen but few that did not yield in two weeks, it is a quite exceptional case that does not yield in a few days, and in the great majority of eyes there is perfect distant vision from the start, if the glasses are commenced before the eye has entirely recovered from the influence of the mydriatic. I have repeatedly investigated cases of supposed inveterate ciliary spasm, and in each instance the supposition has been found to have no substantial basis.

But certain things must be borne in mind. First, that the glass that gives the best correction at 4 or 6 metres is not the correcting glass for the total H., but is an over-correction of $\frac{1}{4}$ or $\frac{1}{6}$ D. I know of no treatise on this subject that takes this into account. It seems like a very small matter. It is often convenient to call rays parallel that come from such a distance; but, strictly speaking, they are not parallel, and the glass that focusses them perfectly on the retina will not perfectly focus parallel rays. This $\frac{1}{4}$ or $\frac{1}{6}$ D. of inaccuracy introduced by the assumption that such rays are parallel, is just the inaccuracy that will make the entire difference between success and failure in the effort to correct the total hyperopia. Patients given a 0.25 D. over-correction, will not become accustomed to it and

see clearly at a distance in any length of time. This inaccuracy must be avoided if you are going to correct the total H. That is, instead of giving the glass that gives the best vision at 4 metres, we must order a lens $\frac{1}{4}$ D. weaker. Another thing to be borne in mind is the aberration of the eye. As I pointed out four years ago (see Trans. American Ophthal. Society, 1888), in the great majority of eyes, the refraction at the margin of the pupil differs from that of the centre. So the lens accepted with the dilated pupil, may be too strong or too weak when the pupil has contracted again.

If with the dilated pupil too weak a lens has been selected, it may be accepted even for really parallel rays, when the pupil is contracted, and this is the only way that we can ever account for the acceptance of the 6 metre correction by an eye that has perfect distant vision without any lens. But if the lens chosen for the dilated pupil is too strong for that portion of the pupil that remains in use after the contraction of the sphincter of the iris, even if the $\frac{1}{4}$ D. for the 4 or 6 metres divergence be deducted from the lens selected under the mydriatic, the remainder will still, for distant vision, be an over-correction, and no eye previously accustomed to perfect distant vision will ever accept it.

Another way in which this notion of the non-acceptance of a full correction has come about, is through the ordering, after an examination without a mydriatic, of a supposed exact correction, or supposed under-correction, which is in reality an over-correction. It comes about in this way. We get the impression from the books, and from our own experience, that latent hyperopia is present in most young eyes. It is found quite generally that young eyes will not, as the influence of a mydriatic goes off, or immediately after it has gone off, accept the convex correction that they did when under the mydriatic.

But my case records have proved conclusively to me that even where this was the case, the latency of the H. is not a fixed condition, but has often appeared after the use of the mydriatic. For instance, an eye showing H. 1.75 D. at first examination, and choosing the + 1.75 D. lens under duboisia, has, a week after the discontinuance of the duboisia, accepted nothing stronger than + 1.25 sph. Now, if I had not made the pre-mydriatic test, I would have supposed this eye brought to me 0.50 D. of its H. latent. And if, acting on this supposition, I had prescribed for the next case of the kind, without using a mydriatic, the strongest lens he could see clearly with, at 4 metres, I might have supposed myself safely inside of a margin of latent H. when no latent H. existed, and actually given an over-correction that would render all things slightly indistinct beyond 20 feet.

My experience shows that young hyperopes

very frequently come to us with none of their H. latent; but you can never certainly know if this be true in any given case, without the use of a mydriatic. I have repeatedly had to remove over-correcting convex lenses that had been ordered without the use of a mydriatic, and have found weak convex cylinders, ordered without mydriasis, where corresponding concaves were needed; the surgeon having been led by what usually happens as to low astigmatism, into prescribing the wrong lenses in the case with which he had to deal at the time.

But if it is admitted that the full convex correction would be accepted in all cases, if steadily worn for a few weeks or days, it will be urged that the great majority of patients will not submit to the inconvenience of those few days or weeks. The difficulty here is psychological. It does exist, I admit, but is serious in a comparatively very few cases.

Our patients usually come to us ready to submit to a good deal, if only we gain and keep their confidence that the ultimate result will be relief. They come ready to submit to the inconveniences of loss of time from business, while they wait day after day in our offices, to submit to the payment of our fees, often to the annoyance of a mydriatic, and the great majority of them will submit to this inconvenience of temporary indistinctness of distant vision, if it is not accompanied by a loss of confidence in the wisdom of their counselor.

In ordering a correction for the total H. a portion of which is latent, it makes all the difference between success and failure, whether we fully warn the patient of the indistinctness of distant vision he is likely to experience, and the length of time it is likely to continue, exaggerating this rather than minifying it, and explain the cause of it; or whether we leave the patient to discover the dimness and its duration for himself. In the one case he will remember our explanations as evidence that we foresaw the difficulty, that we knew what we were about. In the other case, he will be liable to regard our explanations as apologies designed to cover up our mistakes. Then this explanation of the annoyance, which may be illustrated by placing glasses before the eyes that produce it, will enable one to judge whether the particular patient will submit.

It may be said that the deductions I have urged on account of the divergence of rays from points 4 or 6 metres distant, and on account of the aberration of the eye, amount in effect to about the same thing as the practice of giving the correction for the manifest H., or of throwing off a certain fixed proportion of the total correction. But they do not; any more than that amounted to exact justice when the ruler cut off the head of one of his subjects on the first day

of each month, not because that particular subject had done anything worthy of the death penalty, but because probably, during the month, some such crime would be committed within his dominion.

MYOPIA.

The unwillingness of surgeons to order the full correction for myopic eyes, notwithstanding the fact that such a correction would give the best distant vision, is probably based wholly on fear of causing increase in the myopia by strain of the accommodation. I know of no sufficient clinical evidence to support the supposition. My experience indicates that the constant wearing of the full correction lenses, no matter what their strength, with careful attention to other points of ocular hygiene, checks promptly and permanently the advance of myopia in the majority of cases. I have recently examined the eyes of a lady who, as a school-girl, suffering from rapid increase of myopia, was given the full correction of the high compound myopic astigmatism over fifteen years ago, and it practically corrects her error of refraction to-day, and her ocular health is now excellent. Experience has led me year by year to order the full correction of higher degrees of myopia, with greater confidence, in any case that habitually has or can get fair binocular vision, such glasses usually being worn by young people for near as well as distant vision.

Let us see on what considerations the contrary practice is founded. Apparently on theoretical considerations which I believe to be incorrect. Iwanoff stated that he found essential differences between the ciliary muscle of the hyperopic and that of the myopic eye. Later investigators have failed to confirm it, and it is probably incorrect. Then many works state that in myopes, because it is less used, the power of accommodation is less than in hyperopes of the same age. My measurements of the power of accommodation indicate no considerable difference. Of course, myopes, putting on strong concave lenses, have great difficulty in near seeing, at first. But this is due simply to the disarrangement of the accustomed relation of accommodation to convergence, is a phenomenon of the period of adaptation, and careful determination of the range of accommodation for each eye singly shows that it is not deficient in accommodative power. Sometimes, indeed, it is essential to break the transition to the full correction, by partial correction; but this is merely a step toward the end, the constant wearing of the full correction.

This statement is not intended to apply with full force to cases of myopia that have given up binocular vision, or where the vision is so poor from other causes that distinct focussing of rays on the retina cannot be fully appreciated, but it does apply strictly to the great mass of cases of myopia.

Another thing that has misled some very careful students, is the fear of increased congestion of the vascular coat from increased functional activity of the ciliary muscle, increasing the intraocular tension.

The belief in increase of the intraocular tension by accommodation is founded on two things, namely: certain experiments on the eyes of lower animals, and the increase of pulsation in the retinal veins on active accommodation. Of the experimental evidence it may be said, that it is quite contradictory; much the better of it, as it appears to me, seeming to show that there is no increase of intraocular tension in the globe with accommodation. But the conditions of the experiment are so different from those of normal human accommodation, that it has very little force one way or the other.

As to the increased pulsation that occurs in pulsating veins under strong accommodation, we must remember that we cannot increase the tension of the ciliary muscle without increasing that of the internal rectus, and if actual convergence does not occur, it is only because the tension of the external rectus is also increased, and in either case the result is necessary increase in the pressure on the globe from without; to which it is far more rational to ascribe the increased pulsation than to a supposititious influence of the accommodation.

I am not inclined to underrate the importance of hyperæmia in producing distension of the globe, but it is pathological hyperæmia, not physiological. I recognize fully the influence of eye-strain in the production of myopia, but it is eye *strain*, not eye *use*, that does it. We must discriminate more sharply between use and abuse. The normal performance of function is just as necessary to health, as the abnormal excess of demand is dangerous to it. And without adducing additional evidence which is at hand, I rest the claim that, for the myopic as for the hyperopic eye, the most favorable conditions for labor that can be imposed on it are, in general, those under which the emmetropic eye works, most nearly brought about by the wearing of the full correction.

Therefore, in my practice and in my teaching, I have laid it down as a cardinal rule to give the full correction for ametropia—a rule to which exceptions are to be made, but only for special, clearly marked and important indications.

DISCUSSION.

DR. G. C. SAVAGE said: There are cases of ametropia in which a full correction cannot be made. For instance, in a case of astigmatism with one eye according to the rule and the other contrary to the rule, if the meridians are one vertical and the other horizontal, full correction can be given; but if the meridians are oblique it

will give rise to confusion, due to oblique direction of the eyes. In myopia in one eye and hyperopia in the other, there is no strain so long as looking through the optical centres of the lenses; but in looking down, for instance, near him, the deviation of the eyes from the optical centres produces confused prismatic action, on account of the contrary prismatic effect of the lenses when oblique. Such lenses can only be tolerated by decentering them. Again, in hyperopia in both or myopia in both eyes, but differing in degree, the same irregular prismatic displacement occurs when not looking through the optical centres, and the muscles are likewise put on a strain.

DR. GEO. M. GOULD: A word as to full correction. It is commonly said by the advocates of full correction that we are to aim to put the eye in an emmetropic condition; that this is the ideal condition we seek to bring about. I deny the major premises *in toto*. The wherefore is correct if the whereas is allowed. I cannot allow it. And for the following reasons:

1. The history of the pair of eyes we are prescribing for is often, and generally, one of abnormal use, of abuse long continued; the eye, from its history, is in an abnormal condition, and cannot be proceeded with as if it were a normally and physiologically reacting organ.

2. Long abnormalism of deficiency or excess of function has begotten organic changes in the eye itself and its innervation mechanism. In hyperopia the ciliary muscle is excessively developed, in myopia it is excessively weakened, in astigmatism it is unphysiologically developed. These organic and functional changes cannot be neutralized quickly, and will continue to mar the results of all cast-iron rules for a time dependent upon the length of evolution of the defect, the peculiarities of reaction, vital forces, temperament, etc.

3. The work these eyes has to do is so far from ideal that abstract rules will not apply. Civilization brutally crushes ocular ideals as ruthlessly as many another. Sewing girls, bookkeepers, literary people, etc., who must work at near range from twelve to sixteen hours a day, cannot listen to ideals, whether ocular or psychical.

Many other reasons conspire to lead me to lend no ear to abstract rules. Sometimes I over-correct hyperopia, sometimes I aim at artificial emmetropia; usually I under-correct. The bitterness of errors, I think, is to fully correct myopia. I might do it in a farmer, but in an urban liver never. So long as one does it I believe many of his patients must finally leave him. Nearly all patients coming to me from other oculists are these examples of full correction. It is selfishly a good plan for us to encourage in others, but I believe it bad for our patients and our science. In myopia it puts the weakened ciliary muscle

to a strain that is the equivalent of an irritating hyperopia of a degree corresponding with the size of the error, the length of continuance, the reacting quality of the organism and the amount of near work to be done. In hyperopia the hypertrophied ciliary muscle will refuse inaction, or even a very partial deprivation of its accustomed work, for months, and if of long evolution, for years. In astigmatism the reaction comes very promptly, and I find that usually full correction is borne very satisfactorily, though even here exceptions occur. Instead of aiming at an ideal emmetropia, I find as a matter of fact I must aim usually at an ideal of slight myopia, varying from 0.37 D. to 1 and even 2 dioptries. In a myope this can be done at once, in a hyperope never at once, except for extreme near work, but often in the course of time, or by means of a second pair of lenses for near work, though presbyopia proper is a long way off.

DR. J. H. THOMPSON finds many cases where in anisometropia the slightest difference in glasses will not be borne. Thinks also it is dangerous to give full correction in myopia.

DR. JACKSON, closing the discussion, said: In high degrees of anisometropia it is necessary to properly decentre the glasses, and this is often unsatisfactory. It is impossible to correct where the difference is greater than 1.5 D. or 2 D. There are cases in which full correction is not practicable, owing, perhaps, to what the patient has been accustomed; but when it can be borne, full correction should always be given.

ONE HUNDRED CASES OF ASTIGMATISM CONTRARY TO THE RULE, AND THE ASSOCIATED SYMPTOMS.

BY G. E. DE SCHWEINITZ, M.D. (UNIV. OF PENN.),
OPHTHALMIC SURGEON TO THE PHILADELPHIA AND CHILDREN'S
HOSPITALS; OPHTHALMOLOGIST TO THE INFIRMARY FOR
NERVOUS DISEASES; LECTURER ON MEDICAL OPHTHALMOLOGY, UNIV. OF PENNSYLVANIA.

Ever since the days when Weir Mitchell called attention to the intimate connection between a variety of headaches and the existence of errors of refraction, before which time this close association had not received at the hands of neurologists extensive study, the literature of ophthalmology and neurology has been burdened with numerous communications upon this relationship, until now the investigation of a case of headache is not complete until the refraction of the eye and the balance of the ocular muscles have been carefully considered. All forms of refraction error are known to be the cause of headaches, and usually it is considered that the presence of astigmatism, either of the simple or compound type, aggravates the amount of the head-pain. It has been stated that when the astigmatism is contrary to the rule, the entire cor-

rection of the error is more absolutely necessary to bring relief, and that its uncorrected presence is more potent in producing general nervous phenomena, than when the astigmatism is according to the rule. More than this, the researches of Schoen on the influence of accommodative strain in the production of glaucoma and cataract are important additions to our knowledge of the influence of astigmatism, both of the usual and unusual varieties, upon the ultimate well being of ametropic eyes. So, also, Theobald, of Baltimore, has studied a number of examples of astigmatism contrary to the rule, and adduced evidence to show that under certain circumstances this condition of refraction may conduce to the development of glaucoma. The following cases were analyzed because they have been under observation for a sufficient length of time to determine in practically all of them the exact value of their correction, and also to have studied the associated symptoms in sufficient detail to demonstrate whether or not they were out of proportion to the character or the amount of the refraction error. In all of the cases a mydriatic was employed, except in those where the use of such a drug was contra-indicated by glaucomatous symptoms. In patients over 45 the mydriatic was homatropine; in those under 45 either atropine or hyoscyamine. Whenever it was necessary the spherical lens required by the age of the patient, was ordered for the purposes of reading and close vision. This glass is not set down in the notes. For the convenience of study they may be gathered into four groups:

1. Cases presenting themselves for treatment on account of optical reasons alone—beginning presbyopia, or dissatisfaction with convex spherical lenses. No pain and no reflex symptoms.

Case 1. Beginning Presbyopia.—M. T., a man aged 41; no headache; no asthenopia; tricky close vision. Healthy fundus, with the exception of slight absorption of the pigment epithelium of the choroid.

O. D. + .25s \bigcirc + .90c axis 15 $\frac{1}{2}$. O. S. + .25s \bigcirc + .75c axis 150 $\frac{1}{2}$. These lenses were entirely satisfactory.

Case 2. Unsatisfactory Reading Glasses (Convex).—F. E., a woman aged 57; no general disease; no ill health or reflex neurosis traceable to eye strain; unsatisfactory reading glasses. Fundus healthy.

O. D. + .50s \bigcirc + .50c axis 15 $\frac{1}{2}$. O. S. + .50s \bigcirc + .50c axis 165 $\frac{1}{2}$.

Case 3. Eye tire and Blurred Vision at Close Work.—L. K. B., a woman aged 30; perfect general health; no headache but unsatisfactory endurance with simple convex lenses. Normal fundus.

O. D. + 2.s \bigcirc + .25c axis H $\frac{1}{2}$. O. S. + 2.25s \bigcirc + .50c axis 165 $\frac{1}{2}$. The desired improvement resulted.

Case 4. High II; Blurred Vision during Reading.—A. E., a woman aged 44; perfect general health; eyes tire and print blurs; the convex reading lenses do not suffice; no headaches and no asthenopia. Healthy, hypermetropic fundus.

O. D. + 4.50s \bigcirc + .25c axis 15 $\frac{2}{3}$ °. O. S. + 5.5 \bigcirc + .25c axis H $\frac{2}{3}$ °.

Case 5. Unsatisfactory Reading Glasses.—D. I., a woman aged 63; good general health with the exception of hay fever; glasses—convex sphericals corresponding to age—do not permit entirely comfortable reading, or sufficient eye endurance. Round, somewhat gray-red discs.

O. D. + 1.5 \bigcirc + .25c axis 150 $\frac{2}{3}$ °. O. S. + 2.5 \bigcirc + .60c axis 30 $\frac{2}{3}$ °. These glasses with a corresponding correction for reading, were satisfactory.

Case 6. No symptoms of Eye strain; "wants new glasses."—C. W., a woman aged 58; perfect general health; has worn glasses for reading purposes for a number of years which recently have not permitted sufficient eye-endurance. These glasses are simple sphericals. There is no headache. Fundus perfectly normal.

O. D. + .25s \bigcirc + .50c axis 15 $\frac{2}{3}$ °. O. D. + .75s \bigcirc + .25c axis 165 $\frac{2}{3}$ °. These lenses have answered a satisfactory purpose.

Case 7. No symptoms of Eye strain; "wants new glasses."—S. W. M., a woman aged 55; perfect general health; has worn glasses for reading for a number of years, which are simple sphericals and have recently not permitted comfort with reading. The patient states that she had iritis in youth, and the left pupil is slightly distorted above. In each eye the discs are rather gray, but there is no decided lesion of the fundus.

O. D. + 1.25c \bigcirc + .25 axis 15 $\frac{2}{3}$ °. O. S. + 1.25c \bigcirc + .75 axis H $\frac{2}{3}$ °. These lenses associated with the proper presbyopic correction have proved entirely satisfactory.

Case 8. Beginning Presbyopia; No Headache.—M. H. T., a woman, aged 44; in perfect general health; complains of some blur of vision at the near point, inability to thread the needle, and slight smarting of the edges of the eyelid; has never worn glasses. In each eye an oval disc; no conus; a fairly healthy eyeground.

O. D. + .25s \bigcirc + 1.25c axis 30 $\frac{2}{3}$ °. O. S. + .50s \bigcirc + .25c axis 150 $\frac{2}{3}$ °. These glasses were entirely satisfactory.

Case 9. Unsatisfactory Reading Glasses; No Headache.—J. J. S., a man, aged 55; has never worn any glasses except those which he bought in stores, and is using at present a + 3 with which he sees indistinctly at times, but otherwise complains of no symptom at all; his general health is good. The ophthalmoscope shows in each eye an oval disc, somewhat gray in its deeper layers, and a slight gray haze of the retina.

O. D. + 1.50s \bigcirc + .25c axis H $\frac{2}{3}$ °. O. S. +

1.25s \bigcirc + .50c axis H $\frac{2}{3}$ °. These lenses combined with a suitable presbyopic correction afforded the relief he desired.

Case 10. Unsatisfactory Reading Glasses; No Headache.—A. B., a woman, aged 52; good general health; complains of some mistiness while attempting to read, and also when looking at a distance; never has had an attack of headache. Wears a convex spherical of + 3 D.; media clear; tension normal. Oval discs with slight veiling of the lower and inner edges.

O. D. + 2.5 \bigcirc + .25c axis H $\frac{2}{3}$ °. O. S. + 1.50s \bigcirc + 1.25c axis H $\frac{2}{3}$ °. These glasses combined with the necessary addition for reading answered her purposes very satisfactorily.

Case 11. Imperfect Presbyopic Correction.—A. W., a woman, aged 48, complains of neither pain in the eye nor headache, but does not see satisfactorily with her reading glass which is + 4; general health good; media clear, discs oval; eyegrounds fairly healthy.

O. D. + 2.5 \bigcirc + .75c axis H $\frac{2}{3}$ °. O. S. + 1.75s \bigcirc + .50c axis H $\frac{2}{3}$ °. These glasses, together with a suitable presbyopic correction placed in bifocals, were eminently satisfactory.

Case 12. Imperfect Presbyopic Correction.—E. W., a man, aged 62, in active business and perfect health, never has had a headache; complains that after reading for some time his vision blurs. He has worn presbyopic glasses, convex sphericals, for a number of years, having changed them at suitable intervals, but until recently has had no feeling of discomfort at all. The ophthalmoscope showed discs not more gray than was natural at his time of life, and the eyegrounds generally healthy.

O. D. + 1.50s \bigcirc + .90c axis 165 $\frac{2}{3}$ °. O. S. + 1.5 \bigcirc + .90c axis H $\frac{2}{3}$ °. The glasses afforded satisfaction.

Case 13. Unsatisfactory Reading Glasses.—J. A., a woman, aged 50, complains that she cannot see distinctly with her reading glasses (+ 3.25); there is occasional slight smarting and burning of the eye lids; no headache; the general health good. In each eye there is a round disc with a slight absorbing crescent at its outer side; the general fundus in good condition.

O. D. + 1. \bigcirc + .25 axis H $\frac{2}{3}$ °. O. S. + 1.25 \bigcirc + .25 axis 30 $\frac{2}{3}$ °. This combined with a suitable spherical for reading gave the desired relief and the indistinct vision disappeared.

Case 14. Insufficient Reading Glasses; Slight Ocular Pain.—C. S. B., a man aged 48, in perfectly good general health, has worn glasses for eight or ten years, always simple, convex sphericals; from time to time he has used his eyes considerably, and also has had pain in them, but never any headache or other symptoms. In each eye there was an oval disc; no conus; rather pallid; the fundus in fair condition. O. D. + 1.25s \bigcirc + .25c axis 165 $\frac{2}{3}$ °. O. S. + .50s \bigcirc +

.65c axis H $\frac{2}{3}$. This combined with a suitable spherical yielded an excellent result.

Case 15. Imperfect Reading Glasses.—J. A., a woman aged 50, complains that during the act of reading she cannot see distinctly, but otherwise, with the exception of slight burning and smarting at the margins of the lids, has no symptoms of eye-strain; the general health is perfectly good; she has worn glasses for a number of years, always a simple spherical. In each eye there was a round disc with slight crescent at the outer side and an absorbing pigment line beyond.

O. D. + 1.5 \bigcirc + .25c axis H $\frac{2}{3}$. O. S. + 1.25s \bigcirc + .25c axis 30 $\frac{2}{3}$. This with a suitable presbyopic correction proved satisfactory.

Case 16. Unsatisfactory Reading Glasses; Slightly Blurred Vision.—M. R. H., a woman aged 54, has worn glasses for many years, but complains that after their use things blur somewhat; there is no pain and no headache, although the patient herself is a delicate woman having lost much sleep owing to the necessity of nursing a prolonged case of illness in her family. In each eye the disc was an oval, the central lymph sheaths full and the color of the papillæ slightly gray.

O. D. + 2.5 \bigcirc + .50c axis 15 $\frac{2}{3}$. O. S. + 2.5 \bigcirc + .50c axis 165 $\frac{2}{3}$. These glasses seem to help her, although the eye endurance has never been great; they certainly proved better than simple sphericals.

Case 17. Imperfect Reading Glasses; No Pain.—E. J. P., a woman aged 58, for years has suffered with a torpid liver and symptoms called dyspeptic probably owing to the same condition; curiously enough there never has been any pain and no headache; she has worn glasses for years, a simple convex spherical for reading. In each eye an oval optic disc, and scattered through the choroid numerous yellowish dots sometimes discrete and sometimes gathered in clusters; the central lymph sheaths full and the discs rather gray.

O. D. + 1.50s \bigcirc + 2.c axis 15 $\frac{2}{3}$. O. S. + 1.5 \bigcirc + .40c axis H $\frac{2}{3}$. These glasses and the suitable additional lenses for reading purposes gave entire satisfaction; indeed the patient complained of no special symptoms, and except for indistinct vision was reasonably well-satisfied with glasses that paid no attention to her astigmatism.

Of these seventeen cases one was under thirty, seven between forty and fifty, and the remaining nine between fifty and sixty-three. In general terms these patients complained very slightly, the chief disability being lack of eye endurance, although in many instances they were people who, glassed as they were with simple convex lenses, yet read and worked at close ranges with comparative comfort. The desired increase in eye endurance came with the addition of the cylinders. It is noteworthy that in fourteen out of

the thirty-four eyes examined the correcting cylinder was as low as 0.25 dioptry; its absence was missed and its presence a relief. The eyegrounds in these cases presented no unusual features, and hence require no comment.

2. Cases characterized by blepharospasm, symptomatic conjunctivitis, œdema of the lids, epiphora, photophobia or muscæ.

Case 1. Blepharospasm.—M. A., a boy aged 9 years; perfect general health; no headache; constant blepharospasm. Oval, over-capillary disc with fine retinal striation.

O. D. + .60c axis H $\frac{1}{3}$. O. S. + .25s \bigcirc + .60c axis H $\frac{1}{3}$. Complete relief of the symptoms.

Case 2. Epiphora and Ocular Pain.—S. E., a man aged 62; very gouty; one attack of iritis; ocular pain and lachrymation with eye use. Gray red discs and remains of former iritis.

O. D. + .75s \bigcirc equals + .75c axis H $\frac{1}{3}$. O. S. + .90s axis H $\frac{1}{3}$. These glasses afforded relief. In addition the patient took anti-gout diet and iodide of soda.

Case 3. Recurring Attacks of Conjunctivitis; Occasional Temple Headache.—C. T., a woman aged 33; general health good; recurring attacks of conjunctivitis and coarse bulbar injection; some temple headache. No fundus lesion except retinal striation.

O. D. + 1.25s \bigcirc + 1.50c axis 165 $\frac{1}{3}$. O. S. + 3.50s \bigcirc + .75c axis 150 $\frac{1}{3}$. These glasses afforded entire relief.

Case 4. Epiphora.—C. U., a man aged 46; good general health; cannot read at night, and all reading produces epiphora. Fundus normal except slight blurring of the nasal edges of the discs.

O. D. + .50c axis H $\frac{1}{3}$. O. S. + .25c axis 15 $\frac{1}{3}$. The epiphora entirely ceased with the use of this correction added to a corresponding reading lens.

Case 5. Muscæ and Photophobia.—M. L., a woman aged 67; feeble general health without definite disease; reading produces photophobia with web-like film rising before the eyes, the center of the film dotted with darker points. Media clear; gray-red discs, edges slightly mellowed.

O. D. + 1.5 \bigcirc × .60c axis H $\frac{1}{3}$. O. S. + 1.5 \bigcirc + .25c axis 30 $\frac{1}{3}$. These glasses relieved the photophobia, but did not at last accounts remove the muscæ.

Case 6. Photophobia and Ocular Pain.—B. L. J., a woman aged 52; has been the subject of nervous exhaustion and recently underwent the rest cure; now considers herself well; reading produces eye-pain and photophobia. Round discs with slight retinal haze.

O. D. + .25s \bigcirc + .50c axis H $\frac{2}{3}$. O. S. + .25s \bigcirc + .50c axis 15 $\frac{2}{3}$. The result was good.

Case 7. Muscæ; Occasional Supraorbital Neu-

ralgia.—C. T. A., a woman aged 56; subject to rheumatism; loses much sleep; muscæ, supraorbital neuralgia and ocular pain; each lens nucleus strongly marked. Oval, rather gray discs and hazy retinas.

O. D. + .60c axis H $\frac{2}{3}$. O. S. + .25s \bigcirc + .25c axis H $\frac{2}{3}$. These glasses markedly relieved the muscæ and the ocular pain, but not the supraorbital neuralgia. This was modified by antirheumatic treatment.

Case 8. Blepharospasm and Left Headache.—A. C. B., a man aged 18; general health good; has blepharospasm, blepharitis and headache chiefly on the left side; the left eye is amblyopic. There are no lesions of the fundus except that the disc on the left side is grayer than normal at his age of life.

O. D. + 1.25s \bigcirc + .25c axis H $\frac{2}{3}$. O. S. + 2.s \bigcirc + 1.25c axis H $\frac{2}{3}$. Complete relief of the symptoms.

Case 9. Edema of Lids; Some General Headache.—S. C. a woman aged 20; in poor general health; subject to tonsillitis; has had several attacks of catarrhal jaundice; eyes troublesome since childhood. The margins of the disc are veiled; tortuous transverse vessels and woolly choroids.

O. D. + 2.s \bigcirc + .90c axis 15 $\frac{2}{3}$. O. S. + 1.50s \bigcirc + 1.25c axis 165 $\frac{2}{3}$. Relief followed. An attack of typhoid fever shortly afterward, prolonged in its course, rendered it difficult to say what value the correction had for the relief of the eye symptoms.

Case 10. Chronic Hyperæmia; Epiphora.—M. M., a woman aged 47, in good general health, constantly using her eyes, complains of burning, lachrymation, and heaviness of the lids. Inspection of the conjunctiva reveals the somewhat characteristic tear-soaked appearance of chronic hyperæmia. In each eye the disc is gray-red, and there is undue amount of retinal haze and opacity of the fibre layer.

O. D. + .25s \bigcirc + .37c axis 15 $\frac{2}{3}$. O. S. + .75s \bigcirc + .25c axis 165 $\frac{2}{3}$. The use of these glasses with the proper reading correction and a local astringent wash produced great relief.

Case 11. Vaso-motor Blepharitis; Asthenopia.—C. A. Y., a woman aged 25, excessively nervous; imagines she is going blind; worried about slight redness of the ciliary margins which grows worse after eye use; states that she cannot read or sew with any comfort; has worn for some time correction very similar to the one given below. Eye-grounds present oval discs; fairly healthy retinas; no conus.

O. D. + 2.25s \bigcirc + .60c axis H $\frac{2}{3}$. O. S. + 3.25s \bigcirc + .90c axis 165 $\frac{2}{3}$. The eyelids improved very considerably under the use of these glasses, although the patient's asthenopia, according to her own statement, did not improve. The field of vision in this case presented more or

less the typical characteristics seen in hysterical eyes.

Case 12. Chronic Hyperæmia of the Conjunctiva.—P. S., a man aged 42, complains of some epiphora and smarting of the eyelids, the conjunctiva of which presents the appearances of hyperæmia; he never has had a headache and has no asthenopia. In each eye the lymph sheaths are full and there is undue broadening of the scleral ring with haziness of the retinas. The patient uses tobacco and alcohol injudiciously, and has done enormous amounts of eye work.

O. D. + 1.75s \bigcirc + .75c axis H $\frac{2}{3}$. O. S. + 1.50s \bigcirc + .75c axis H $\frac{2}{3}$. These glasses together with a slight antiseptic wash afforded relief; the patient was not, however, under observation very long.

Case 13. Epiphora; Slight Ocular Pain.—J. R., a boy aged 8, complains of slight pain in his eyes and constant watering, especially after the act of reading; scarlet fever in youth, but no recent illness; headaches practically never present. In each eye an oval, unduly capillary disc and typical shot-silk retina.

O. D. + 1.50s \bigcirc + .90c axis 45 $\frac{2}{3}$. O. S. + 1.25s \bigcirc + .60c axis 165 $\frac{2}{3}$. One month later reports himself better, though the eyes occasionally grow red; watering has stopped; there are a few swollen lymph follicles on the retrotarsal folds.

These thirteen cases varied in age from eight to sixty-seven years, and presented as their most prominent complaint one or other of the symptoms noted in the group heading—symptoms commonly seen in all forms of refraction error, and occurring quite as frequently in cases of usual astigmatism, and even in simple hypermetropia and myopia. In two of the cases evidence of general disease required appropriate constitutional remedies, and in one hysteria was a strong factor. It is again noteworthy in four of the cases that the addition of a weak cylinder to a spherical glass which previously had been worn for reading produced a result not attained by the former correction, and that in six of the examined eyes the astigmatism was correction by a 0.25 cylinder.

3. Cases characterized by various types of headaches aggravated by the use of the eyes.

Case 1. Peri-ocular Pain and Occipital Headache.—L. M., a woman aged 56; in delicate health; nausea and backache; peri-ocular, frontal and occipital headache. Grey-red discs, distended lymph sheaths, areas of fine, yellowish-white spots in macula. Urine slightly albuminous and containing hyaline tube casts.

O. D. + .25s \bigcirc + .90c axis H $\frac{1}{3}$. O. S. + .50s \bigcirc + .75c axis H $\frac{1}{3}$. The presence of Bright's disease in this case rendered it impossible to judge of the value of the glasses in relieving the headache.

Case 2. Nocturnal Headache.—B. C., a woman aged 40; general health good; misty vision and a feeling of fulness in head; nocturnal headaches after evening use of eyes; discs too capillary, and faint retinal haze.

O.D. + 1.25 \odot + .90 axis 10 $\frac{1}{3}$. O.S. + 1.25 \odot + .50 axis 165 $\frac{1}{3}$. Entire relief resulted.

Case 3. Severe Supraorbital Neuralgia.—D. W., a man aged 61; chronic rheumatism; gouty ancestry; severe supraorbital neuralgia; failing vision especially in O.D.

O.D. + 1.5 \odot + .50c axis 15 $\frac{2}{3}$. O.S. + 1.5 \odot + .50c axis H $\frac{2}{3}$. In the right eye greyed disc and unduly prominent scleral ring; field contracted. In left eye fundus normal except broadening of the scleral ring. Reading power improved; supraorbital neuralgia not relieved; this was probably rheumatic.

Case 4. Severe Frontal Headache.—J. M., a girl aged 17; general health usually good; slight menstrual derangement; frontal headache severely aggravated by eye use. Fundus normal.

O.D. + 1.25s \odot + .60c axis H $\frac{2}{3}$. O.S. + 1.25s \odot + .60c axis 165 $\frac{2}{3}$. These glasses afforded entire relief except during the menstrual epoch when considerable asthenopia appeared.

Case 5. Frontal Headache.—S. W., a young man aged 18; general health good; no complaint except frontal headache after reading or study; discs normal in color; scleral rings unduly broad; veins and lymph sheaths distended.

O.D. + 1.5 \odot + .90c axis H $\frac{1}{3}$. O.S. + 1.5 \odot + 1.25c axis 165 $\frac{1}{3}$. The result was entirely satisfactory.

Case 6. Right-sided Headache, Neuralgic in Type.—M. D., a woman aged 59; delicate health, the result of a long standing fistula in ano and a severe attack of typhoid fever; cannot read with any comfort, severe headache the invariable result; is wearing simple sphericals.

O.D. + 1.5 \odot + .50c axis H $\frac{1}{3}$. O.S. + 1.25s \odot + .25c axis H $\frac{1}{3}$. Much relief followed the use of the new glasses.

Case 7. Peri-orbital Pain and General Headache.—P. D. E., a woman aged 30, feeble general health without definite disease; severe general headaches and photophobia aggravated by eye use. Oval discs, nasal edges veiled, choroids woolly.

O.D. + .25s \odot + .50c axis H $\frac{1}{3}$. O.S. + .50s \odot + .50c axis H $\frac{1}{3}$. Greatly improved in all respects without the use of general medication.

Case 8. Constant Temple Headache.—M. D. G., a boy aged 18, general health good; constant temple headache with some lachrymation. Oval, over-capillary discs, with veiling of the nasal edges.

O.D. + .50s \odot + .50c axis 16 $\frac{2}{3}$. O.S. + .50s \odot + .25c axis 165 $\frac{2}{3}$. Satisfactory results.

Case 9. Constant Left sided Head Pain.—H.

R. C., a man aged 90, general health perfectly good; dull ocular pain and sharp left-sided headache, with some photophobia. In the right eye round disc, color good, but scleral ring too plainly marked; left eye, oval disc, gray, veins and lymph sheaths full.

O.D. + .90s \odot .50c axis H $\frac{2}{3}$. O.S. + 1.5 \odot + .50c axis 165 $\frac{2}{3}$. There was entire relief.

Case 19. "Sick Headache."—M. A., a woman aged 50, good general health; numerous sick headaches brought on by eye use, with unsatisfactory reading power. Oval, healthy discs.

O.D. + 1.50s \odot + .50c axis 150 $\frac{2}{3}$. O.S. + 1.50s \odot + .50c axis 30 $\frac{2}{3}$. These glasses afforded relief when combined with proper reading lenses.

Case 11. Occipital Headache.—S. M., a woman aged 47, cardiac asthma from mitral disease, has had rheumatism; severe occipital headache aggravated by eye use, ordinary convex sphericals useless.

O.D. + .50s \odot + .60c axis 15 $\frac{2}{3}$. O.S. + .50s \odot + 1.c axis 165 $\frac{2}{3}$. The occipital headache had disappeared when the patient was last seen.

Case 12. Occipital Headache.—J. H. T., a man aged 38, general health good; has worn glasses for four years (+ 1.5); recently complains of not seeing well and pain in the occiput after eye use. In each eye an oval disc, with a slight patch of choroiditis at the outer margin; central lymph sheaths full.

O.D. + 1.50s \odot + .50c axis H $\frac{2}{3}$. O.S. + 1.50s \odot .50c axis H $\frac{2}{3}$. The result was perfectly satisfactory.

Case 13. Severe Brow Pain.—M. L., a girl aged 16, slender, anæmic, occasional dysmenorrhœa; for two years has suffered with violent attacks of brow pain, slight ache being more or less constant, and the explosions of headache being severe enough to put the patient to bed. They were often noted on Saturday or Sunday. The ophthalmoscope reveals in each eye an oval optic disc, unduly capillary, and all the edges blurred by a hazy retina; in other words, a typical eye strain eye-ground.

O.D. + .75s \odot + .60c axis 15 $\frac{2}{3}$. O.S. + .75s \odot + .75c axis H $\frac{2}{3}$. These glasses, together with discontinuance of the studies, the administration of iron and occasional doses of bromide of lithium, revolutionized this girl. She is to-day practically free from headaches, or at least they come with great rarity. Her color has improved, her hæmoglobin has mounted to normal, and the eye-grounds have vastly improved. It should be noted, however, that with the glasses there was careful regulation of her habit of life, and the almost continuous use of iron in the form of Bland's pills.

Case 14. Severe General Headache.—H. F., a woman aged 30, from early childhood has been

subject to violent general headaches, considering herself fortunate if she passed a day without some pain in the head; this was invariably brought on in a violent degree by use of the eyes. In girlhood she was removed from school on this account. With this exception, there is no general disturbance. Curiously enough, her eyes were never examined. Each eye presented an oval optic disc of fairly good color, and no changes in the fundus.

O. D. + 2.75s \bigcirc + .50c axis H $\frac{20}{90}$. O. S. + 4.50s \bigcirc + .50c axis H $\frac{20}{90}$. Very marked relief followed the use of these glasses.

Case 15. Violent Headaches of the Migrainal Type.—A. J., a woman aged 50, had for years suffered with violent headache, worse in the eye, top of the head and back of the ear, generally one-sided, without positive prodromes, and sometimes followed by nausea; has tried all manner of medication, and on the examinations of very competent general practitioners was pronounced to be free from constitutional reasons for such headache. She is, however, an anæmic woman, slender, and readily worried, having met with considerable business reverses. The eye-grounds were healthy; in each eye an oval optic disc of about normal color.

O. D. + .75s \bigcirc + .75c axis 30 $\frac{20}{90}$. O. S. + .75s \bigcirc + .75c axis 165 $\frac{20}{90}$. These glasses did not cure the headache; in fact, at the last account she was not relieved by them except as aids to reading. She was a peculiar, somewhat vain, old maid, and declined to wear the distance glasses. It is possible that had she consented to the constant use of glasses the result might have been better.

Case 16. Violent Temple and Brow Headache.—W. J., a woman aged 35, except for occasional attacks of gastralgia, probably has a symptom of one of the types of dyspepsia usually induced by imprudence in eating, is in good general health. She suffers from violent temple and brow headache, and is subject to excessive exacerbations of these pains. In each eye a slightly oval, unduly capillary optic disc; the retinas fairly good. She has worn + 4.50 without relief.

O. D. + 5.50s \bigcirc + .50c axis 15 $\frac{20}{90}$. O. S. + 7.50s \bigcirc + .60c axis 165 $\frac{20}{90}$. These glasses cured the headaches.

Case 17. Typical School Headaches.—A girl aged 13, in good general health, complains of brow pain at the end of each school hour, and that the eyes feel as if they were being pushed in. Oval discs, slight crescent and some retinal haze.

O. D. + 1.75s \bigcirc + .25c axis 150 $\frac{20}{90}$. O. S. + 1.75s \bigcirc + .25c axis H $\frac{20}{90}$. No headaches occurred unless she laid aside her glasses.

Case 18. Constant Headaches.—S. E. C., a woman aged 45, states that since her 15th year she has had constant headache, its chief location being in the brow and temple; she is fairly well

nourished without constitutional taint, but with a neurasthenic tendency and a habit of trying all manner of doctors. Remedies have proved unavailing in her headache; five graduated tenotomies have been done; these, she states, relieved for a time the headaches which now, however, are constant and severe. She wears for distance + .50 and for reading + 2.50. Each disc an oval, its surface slightly œdematous and all edges slightly hazy; numerous lymph reflexes.

O. D. + 1.s \bigcirc + .25c axis 15 $\frac{20}{90}$. O. S. + 1.s \bigcirc + .50c axis 165 $\frac{20}{90}$. After wearing these glasses for some time she states that they help her eyes but the headache continues to be present, although not so severe, in the brow and temple. She has undergone careful six-weeks rest cure and is generally much improved.

Case 19. Violent Scattered Head-pain; No Relief from Drugs.—A. B. H., a man aged 35, has had no serious illness since his 17th year, when he suffered from scarlet fever, but had a slight heat stroke eight years ago. He is very bilious; works in tobacco, but uses the drug moderately. His present trouble began five years ago in the form of shooting pains in the head, previous to which time he suffered from sick headaches. These pains located themselves in different spots, and are intensely violent and neuralgic in type. In each eye a round disc with some patches of white over the central vessels; rather full veins, but otherwise normal eyegrounds.

O. D. + .50c axis 150 $\frac{20}{90}$. O. S. + .37c axis 30 $\frac{20}{90}$. With the exception of a few doses of croton chloral hydrate the patient had no remedies after the prescription of these comparatively weak cylinders, and yet the relief was almost immediate and has continued ever since, the treatment having been instituted many months ago.

Case 20. Periorbital Pain.—G. P. S., a woman aged 49, rather delicate in constitution and yet without organic disease, complains of a peculiar pain, which is described as drawing in the brow and over the eye after reading and writing; this pain speedily produces nausea. In each eye an oval disc, the edges slightly blurred by hazy retinas.

O. D. + 2.s \bigcirc + .25c axis H $\frac{20}{90}$. O. S. + 1.75s \bigcirc + .50c axis 150 $\frac{20}{90}$. These glasses combined with suitable presbyopic correction, were of great assistance, and reading and writing is now done with comparative ease, although eye endurance is not great. The previous correction was similar except that the astigmatism had been unnoted.

Case 21. Vertex and Occipital Headache.—M. J. A. a woman aged 51, is excessively anæmic, having had two attacks of hæmatemesis, in the last of which she nearly perished, probably depending upon ulcer of the stomach; she is deaf from catarrhal disease of the Eustachian tubes.

Numerous muscæ float before each eye. In each the edges of the disc slightly hazy, the choroid a little woolly, a few yellowish dots scattered through the eyeground but no hæmorrhages; the color of the disc pallid.

O. D. + 1.75s \bigcirc + .50c axis H $\frac{2}{3}$. O. S. + 1.75s \bigcirc + .60c axis 15 $\frac{2}{3}$. These glasses and a suitable presbyopic correction combined in bifocals, may have produced some relief, but the eyes were far from comfortable and the eye endurance exceedingly limited. It could not reasonably be expected that any great impression would be made in a woman whose hæmoglobin was so much below the normal from excessive hæmorrhages.

Case 22. General Headache.—A. H. T., a woman aged 30, always complained of weak eyes; never has had any severe illness. In childhood fell upon the head, without, however, producing a fracture; in early childhood had convulsions attributed to indigestion; for years has suffered with violent headaches beginning in the eyes, becoming general and ending in nausea. Drugs have palliated but done nothing more. In each eye the disc is oval, the surrounding retina hazy and the surface of the papillæ a little woolly.

O. D. + .75s \bigcirc + .25c axis 30 $\frac{2}{3}$. O. S. + .75s + .25c axis 150 $\frac{2}{3}$. After wearing these glasses for several months she reported an entire absence, with one exception, of headaches.

Case 23. Brow Headache After Study.—F. R., a boy aged 14, had diphtheria and scarlet fever in infancy, but is perfectly well now; complains of the ordinary brow pain after evening study hour so common in children; occasionally the headache becomes general. With the exception of unduly full veins which are slightly tortuous there are no changes in the eyeground.

O. D. + 1.25s \bigcirc + .50c axis H $\frac{2}{3}$. O. S. + 1.50s \bigcirc + .25c axis H $\frac{2}{3}$. The relief was complete.

Case 24. Severe Occipital Headache.—E. M., a woman aged 45, has had a complication of troubles which may briefly be stated as double vision from paralysis of one or other of the ocular muscles (it is not known now which) followed by Bell's palsy, the remains of which are still apparent, and having had as her most recent illness a severe miscarriage, one other having also occurred, in all instances the probable result of specific taint. There were no changes in the eyeground to indicate constitutional disease and she sought relief for violent occipital headache.

O. D. + 1.s \bigcirc + .50c axis 30 $\frac{2}{3}$. O. S. + 1.s \bigcirc + .75c axis 150 $\frac{2}{3}$. This, or a correction very nearly like it, together with a suitable presbyopic correction, she had worn for some time and with some relief, but the headache continued. The correction was gone over again and a slight change made in the cylinders, without much relief to the headache, which also did not yield to antispecific treatment. A thorough examination

of the urine revealed some albumen and here and there a tube cast. Under proper diet, combined with Basham's mixture and small doses of bichloride of mercury, the occipital pain disappeared. In this instance it is evident that the astigmatism was not the cause of the pain, and that its correction consequently yielded no result.

Case 25. Violent General Headache.—G. S., a woman aged 31, for four years has suffered with violent headaches, somewhat relieved but by no means set aside by glasses which properly correct her astigmatism. One year ago she had nervous prostration, and has suffered at times with rheumatic pains in the shoulders; otherwise the health appears to be good. In each eye there is an oval, distinctly gray optic disc.

O. D. + 3.s \bigcirc + .75c axis H $\frac{2}{3}$. O. S. + 2s. \bigcirc + .50c axis H $\frac{2}{3}$. Three months after the correction the patient reported that she had scarcely any headache, although previous to that time it was rare to go a day without one. It is interesting to note that in this case she previously wore a correction of her astigmatism, just half of the amount having been ordered, with almost no correction of the hypermetropia and with no good result.

Case 26. "Sick Headaches."—E. L. S., a woman aged 45, some years ago had typhoid fever; since then has been well, but has lost much sleep by nursing; wears simple sphericals which are not satisfactory; always has had much headache, which begins over left eye, spreads through head to occiput, and also has many "sick headaches," beginning in the same way. The optic discs are pallid, with marked scleral rings surrounding them; otherwise no changes.

O. D. + .60s \bigcirc + .25c axis H $\frac{2}{3}$. O. S. + .60s \bigcirc + .25c axis H $\frac{2}{3}$. Three months after the use of these glasses, together with the necessary convex addition for reading, which was combined with a 2.5° prism base in, the patient reported herself much better.

Case 27. Severe Frontal Headache.—W. J. S., a woman aged 48, with the exception of considerable nervousness and ready succumbing to fatigue, is in good general health. She has worn glasses for twenty-three years, always simple sphericals, and for years has suffered with violent pain beginning in the forehead and passing to the occiput, coming in spells sometimes lasting for two days at a time. These headaches are induced not alone by reading or eye work, but by any fatigue. There are faint striæ in the far periphery of each lens. The discs are oval, of good color, maculæ normal; some filling of the central lymph sheaths.
